Soon after the discovery of carbon nanotubes, it was realized that the theoretically predicted mechanical properties of these interesting structures—including high strength, high stiffness, low density and structural perfection—could make them ideal for a wealth of technological applications. The experimental verification, and in some cases refutation, of these predictions, along with a number of computer simulation methods applied to their modeling, has led over the past decade to an improved but by no means complete understanding of the mechanics of carbon nanotubes. We review the theoretical predictions and discuss the experimental techniques that are most often used for the challenging tasks of visualizing and manipulating these tiny structures. We also outline the computational approaches that have been taken, including *ab initio* quantum mechanical simulations, classical molecular dynamics, and continuum models. The development of multiscale and multiphysics models and simulation tools naturally arises as a result of the link between basic scientific research and engineering application; while this issue is still under intensive study, we present here some of the approaches to this topic. Our concentration throughout is on the exploration of mechanical properties such as Young's modulus, bending stiffness, buckling criteria, and tensile and compressive strengths. Finally, we discuss several examples of exciting applications that take advantage of these properties, including nanoropes, filled nanotubes, nanoelectromechanical systems, nanosensors, and nanotube-reinforced polymers. This review article cites 349 references.

1 INTRODUCTION

The discovery of multi-walled carbon nanotubes (MWCNTs) in 1991 [1] has stimulated ever-broader research activities in science and engineering devoted entirely to carbon nanostructures and their applications. This is due in large part to the combination of their expected structural perfection, small size, low density, high stiffness, high strength (the tensile strength of the outer most shell of MWCNT is approximately 100 times greater than that of aluminum), and excellent electronic properties. As a result, carbon nanotubes (CNT) may find use in a wide range of applications in material reinforcement, field emission panel display, chemical sensing, drug delivery, and nanoelectronics.

Indeed, NASA is developing materials using nanotubes for space applications, where weight-driven cost is the major concern, by taking advantage of their tremendous stiffness and strength. Composites based on nanotubes could offer strength-to-weight ratios beyond any materials currently available. Companies such as Samsung and NEC have demonstrated product quality devices utilizing carbon nanotubes for field emission display [2,3] and have invested tremendously. Such devices have shown superior qualities such as low turn-on electric field, high emission current density, and high stability. With the advance of materials synthesis and device processing capabilities, the importance of developing and understanding nanoscale engineering devices has dra-

Transmitted by Associate Editor AK Noor

matically increased over the past decade. Compared to other nanoscale materials, single-walled carbon nanotubes (SWCNT) possess particularly outstanding physical and chemical properties. SWCNTs are remarkably stiff and strong, conduct electricity, and are projected to conduct heat even better than diamond, which suggests their eventual use in nanoelectronics. Steady progress has been made recently in developing SWCNT nanodevices and nanocircuits [4,5], showing remarkable logic and amplification functions. SWCNTs are also under intensive study as efficient storage devices, both for alkali ions for nanoscale power sources and for hydrogen for fuel cell applications.

On other fronts, CNTs also show great potential for biomedical applications due to their biocompatibility and high strength. The current generation of composites used for replacement of bone and teeth are crude admixtures of filler particles (often glass) that have highly inadequate mechanical properties compared to skeletal tissue. Fiber-based composites have been investigated in the past, but have not worked well because of eventual degradation of the filler/matrix interface, usually due to attack by water. Thus, a major issue is interfacial stability under physiological conditions. Graphitic materials are known to resist degradation in the types of chemical environments present in the body. Recent demonstration of CNT artificial muscle [6] is one step along this direction and promises a dramatic increase in work density output and force generation over known technologies, along with the ability to operate at low voltage. CNTs are also being considered for drug delivery: they could be implanted at the sites where a drug is needed without trauma, and slowly release a drug over time. They are also of considerable promise in cellular experiments, where they can be used as nanopipettes for the distribution of extremely small volumes of liquid or gas into living cells or onto surfaces. It is also conceivable that they could serve as a medium for implantation of diagnostic devices.

The rapid pace of research development as well as industry application has made it necessary to summarize the current status about what we have known and what we do not know about this particularly interesting nanostructure. A number of excellent reviews on the general properties of CNTs can be found in [7–9]. In this review article, we have made this effort with emphasis on the mechanical aspects. The article is organized as follows: The next section focuses on the mechanical properties of CNTs. This includes the basic molecular structure, elastic properties, strength, and crystal elasticity treatment. Section 3 summarizes the current experimental techniques that were used in the measurement of the mechanical properties of CNTs. A brief discussion on the challenges in the experiment is also presented. Various simulation methods are discussed in Section 4. The length scale spans from quantum level to continuum level. This highlights the multiscale and multiphysics features of the nanoscale problem. Section 5 considers a few important mechanical applications of CNTs. Finally, conclusions are made in Section 6.

2 MECHANICAL PROPERTIES OF NANOTUBES

2.1 Molecular structure of CNTs

2.1.1 Bonding mechanisms

The mechanical properties of CNTs are closely related to the nature of the bonds between the carbon atoms. The bonding mechanism in a carbon nanotube system is similar to that of graphite, since a CNT can be thought of as a rolled-up graphene sheet. The atomic number for carbon is 6, and the atom electronic structure is $1s^2 2s^2 2p^2$ in atomic physics notation. For a detailed description of the notation and the structure, readers may refer to basic textbooks on general chemistry or physics [10]. When carbon atoms combine to form graphite, sp^2 hybridization [10] occurs. In this process, one s -orbital and two p -orbitals combine to form three hybrid sp^2 -orbitals at 120° to each other within a plane (shown in Fig. 1). This in-plane bond is referred to as a σ -bond (*sigma*-bond). This is a strong covalent bond that binds the atoms in the plane, and results in the high stiffness and high strength of a CNT. The remaining p -orbital is perpendicular to the plane of the σ -bonds. It contributes mainly to the interlayer interaction and is called the π -bond (*pi*-bond). These out-of-plane, delocalized π -bonds interact with the π -bonds on the neighboring layer. This interlayer interaction of atom pairs on neighboring layers is much weaker than a σ -bond. For instance, in the experimental study of *shell-sliding* [11], it was found that the shear strength between the outermost shell and the neighboring inner shell was 0.08 MPa and 0.3 MPa according to two separate measurements on two different MWCNTs. The bond structure of a graphene sheet is shown in Fig. 1.

2.1.2 From graphene sheet to single-walled nanotube

There are various ways of defining a unique structure for each carbon nanotube. One way is to think of each CNT as a result of rolling a graphene sheet, by specifying the direction of rolling and the circumference of the cross-section. Shown in Fig. 2 is a graphene sheet with defined roll-up vector \mathbf{r} . After rolling to form a NT, the two end nodes coincide. The notation we use here is adapted from [8,12,13]. Note that \mathbf{r}

Fig. 1 Basic hexagonal bonding structure for one graphite layer (the *graphene sheet*); carbon nuclei shown as filled circles, out-of-plane π -bonds represented as *delocalized* (dotted line), and σ -bonds connect the C nuclei in-plane.

(bold solid line in Fig. 2) can be expressed as a linear combination of base vectors *a* and *b* (dashed line in Fig. 2) of the hexagon, *ie*,

$$r = na + mb$$

with *n* and *m* being integers. Different types of NT are thus uniquely defined by the values of *n* and *m* and the ends are closed with caps for certain types of fullerenes (Fig. 3).

Three major categories of NT can also be defined based on the chiral angle θ (Fig. 2) as follows

$$\theta = 0, \quad \text{“Zigzag”}$$

$$0 < \theta < 30, \quad \text{“Chiral”}$$

$$\theta = 30, \quad \text{“ArmChair”}$$

Based on simple geometry, the diameter *d* and the chiral angle θ of the NT can be given as

$$d = 0.783 \sqrt{n^2 + nm + m^2} \text{ \AA}$$

$$\theta = \sin^{-1} \left[\frac{\sqrt{3}m}{2(n^2 + nm + m^2)} \right]$$

Most CNTs to date have been synthesized with closed ends. Fujita *et al* [14] and Dresselhaus *et al* [8,15] have shown that NTs which are larger than (5,5) and (9,0) tubes can be capped. Based on Euler’s theorem of polyhedra [16], which relates the numbers of the edges, faces and vertices, along with additional knowledge of the minimum energy structure

of fullerenes, they conclude that any cap must contain 6 pentagons that are isolated from each other. For NTs with large radius, there are different possibilities of forming caps that satisfy this requirement. The experimental results of Iijima *et al* [17] and Dravid [18] indicate a number of ways that regular-shaped caps can be formed for large diameter tubes. *Bill*-like [19] and semi-toroidal [17] types of termination have also been reported. Experimental observation of CNTs with open ends can be found in [17].

2.1.3 Multi-walled carbon nanotubes and scroll-like structures

The first carbon nanotubes discovered [1] were multi-walled carbon nanotubes (shown in Figs. 4 and 5). Transmission electron microscopy studies on MWCNTs suggest a Russian doll-like structure (nested shells) and give interlayer spacing of approximately ~ 0.34 nm [20,21], close to the interlayer separation of graphite, 0.335 nm. However, Kiang *et al* [22] have shown that the interlayer spacing for MWCNTs can range from 0.342 to 0.375 nm, depending on the diameter and number of nested shells in the MWCNT. The increase in intershell spacing with decreased nanotube diameter is attributed to the increased repulsive force as a result of the high curvature. The experiments by Zhou *et al* [21], Amelinx *et al* [23], and Lavin *et al* [24] suggested an alternative “scroll” structure for some MWCNTs, like a cinnamon roll. In fact, both forms might be present along a given MWCNT and separated by certain types of defects. The energetics

Fig. 4 Upper left: High resolution transmission electronic microscopy (HRTEM) image of an individual MWCNT. The parallel fringes have ~ 0.34 nm separation between them and correspond to individual layers of the coaxial cylindrical geometry. Bottom left: HRTEM image showing isolated SWCNT as well as bundles of such tubes covered with amorphous carbon. The isolated tubes shown are approximately 1.2 nm in diameter. Top right: HRTEM image showing the tip structure of a closed MWCNT. The fringe (layer) separation is again 0.34 nm. Top right: The tip structure of a conical end. Bottom right: The image of a MWCNT showing the geometric changes due to the presence of five and seven membered rings (position indicated in the image by P for pentagon and H for heptagon) in the lattice. Note that the defects in all the neighboring shells are conformal (from [25]).

analysis by Lavin *et al* [24] suggests the formation of a scroll, which may then convert into a stable multi-wall structure composed of nested cylinders.

2.2 Modeling of nanotubes as elastic materials

2.2.1 Elastic properties: Young's modulus, elastic constants, and strain energy

Experimental fitting to mechanical measurements of the Young's modulus and elastic constants of nanotubes have been mostly made by assuming the CNTs to be elastic beams. An extensive summary is given in Section 2.2.2. Aside from the use of the beam assumption, there are also experimental measurements that were made by monitoring the response of a CNT under axial load. Lourie and Wagner [27] used micro-Raman spectroscopy to measure the compressive deformation of a nanotube embedded in an epoxy matrix. For SWCNT, they obtained a Young's modulus of 2.8–3.6 TPa, while for MWCNT, they measured 1.7–2.4 TPa.

Yu *et al* [28] presented results of 15 SWCNT bundles under tensile load and found Young's modulus values in the range from 320 to 1470 GPa (mean: 1002 GPa). The stress versus strain curves are shown in Fig. 6. Another experiment performed by Yu *et al* [29] on the tensile loading of MWCNTs yielded a Young's modulus from 270 to 950 GPa (Fig. 7). It should be pointed out that concepts such as Young's modulus and elastic constants belong to the framework of continuum elasticity; an estimate of these material parameters for nanotubes implies the continuum assumption. Since each individual SWCNT only involves a single layer of rolled graphene sheet, the thickness t will not make any sense until it is given based on the continuum assumption. In

the above-mentioned experiments, it is assumed that the thickness of the nanotube is close to the interlayer distance in graphite, ie, 0.34 nm.

In the following, we focus on the theoretical prediction of these parameters. Unless explicitly given, a thickness of 0.34 nm for the nanotube is assumed. The earliest attempt to predict Young's modulus theoretically seems to have been made by Overney *et al* [30]. Using an empirical Keating Hamiltonian with parameters determined from first principles, the structural rigidity of (5,5) nanotubes consisting of 100, 200, and 400 atoms was studied. Although the values are not explicitly given, it was later pointed out by Treacy *et al* [31] that the results from Overney *et al* implied a Young's modulus in the range of 1.5 to 5.0 TPa. The earliest energetics analysis of CNTs was presented by Tibbetts [32] using elastic theory. He pointed out that the strain energy of the tube is proportional to $1/R^2$ (where R is the radius of the CNT). Ruoff and Lorents [33] suggested the use of elastic moduli of graphite by neglecting the change in the atomic structure when a piece of graphene sheet is rolled into a nanotube. Since the mechanical behavior of single-crystal graphite is well understood, it would be a good approximation to use the

in-plane modulus (1.06 TPa of graphite). However, whether such an approximation is good for SWCNTs with small radius was not known.

Robertson *et al* [34] examined the energetics and elastic properties of SWCNTs with radii less than 0.9 nm using both Brenner's potential [35] and first-principles total energy methods. Their results showed a consistent linear proportionality to $1/R^2$ of the strain energy, which implies that small deformation beam theory is still valid even for the small radius limit. An elastic constant (C_{11}) close to that of graphite was predicted using the 2nd set of parameters from Brenner's potential [35]; however, it was also shown that the 1st set of parameters from the same potential results in excess stiffness. Gao *et al* [36] carried out a similar study on SWCNTs of larger radius (up to 17 nm) with a potential that is derived from quantum mechanics. A similar linear relation of the strain energy to $1/R^2$ was found. By computing the second derivative of the potential energy, values of Young's modulus from 640.30 GPa to 673.49 GPa were obtained from the MD simulation for closest-packed SWCNTs.

Yakobson *et al* [37] compared particular molecular dynamics (MD) simulation results to the continuum shell model [38] and thereby fitted both a value for Young's modulus (~ 5.5 TPa) and for the effective thickness of the CNTs ($t=0.066$ nm). Lu [39] derived elastic properties of SWCNTs and MWCNTs using an empirical model in his MD simulation. A Young's modulus of ~ 1 TPa and a shear modulus of ~ 0.5 TPa were reported based on a simulated tensile test. Lu also found from his simulation that factors such as chirality, radius and the number of walls have little effect on the value of Young's modulus. Yao *et al* [40] used a similar approach but with a different potential model and obtained a Young's modulus of approximately 1 TPa. In addition, they treated the dependence of Young's modulus on both the radius and chirality of the tube. They employed an MD model that includes bending, stretching and torsion terms, and their results showed that the strain in the tube is dominated by the torsional terms in their model. An alternate method is to derive Young's modulus based on the energy-per-surface area rather than per-volume. This was used in the study by Hernandez *et al* [41]. Using a nonorthogonal tight-binding scheme, they reported a *surface Young's modulus* of 0.42 TPa-nm, which, when converted to Young's modulus assuming the thickness of 0.34 nm, resulted in a value of 1.2 TPa. This value is slightly higher than that obtained by Lu [39].

Zhou *et al* [42] estimated strain energy and Young's modulus based on electronic band theory. They computed the total energy by taking account of all occupied band electrons. The total energy was then decomposed into the rolling energy, the compressing or stretching energy, and the bending energy. By fitting these three values with estimates based on the continuum elasticity theory, they obtained Young's modulus of 5.1 TPa for SWCNT having an effective wall thickness of 0.71 Å. Note that this is close to the estimate by Yakobson *et al* [37], since the rolling energy and stretching energy terms were also included in the shell theory that Ya-

kobson *et al* used. In addition, the accuracy of the continuum estimate was validated by the derivation of a similar linear relation of the strain energy to $1/R^2$.

Although no agreement has been reached among these publications regarding the value of the Young's modulus at this moment, it should be pointed out that a single value of Young's modulus cannot be uniquely used to describe both tension/compression *and* bending behavior. The reason is that tension and compression are mainly governed by the in-plane σ -bond, while pure bending is affected mainly by the out-of-plane π bond. It may be expected that different values of elastic modulus should be obtained from these two different cases unless different definitions of the thickness are adopted, and that is one reason that accounts for the discrepancies described above. To overcome this difficulty, a consistent continuum treatment in the framework of crystal elasticity is needed, and we present this in Section 2.4.

2.2.2 Elastic models: Beams and shells

Although CNTs can have diameters only several times larger than the length of a bond between carbon atoms, continuum models have been found to describe their mechanical behavior very well under many circumstances [43]. Indeed, their small size and presumed small number of defects make CNTs ideal systems for the study of the links between atomic motion and continuum mechanical properties such as Young's modulus and yield and fracture strengths. Simplified continuum models of CNTs have taken one of two forms: simple beam theory for small deformation and shell theory for larger and more complicated distortions.

Assuming small deformations, the equation of motion for a beam is

$$\rho A \frac{\partial^2 u}{\partial t^2} + EI \frac{\partial^4 u}{\partial x^4} = q(x) \quad (1)$$

where u is the displacement, ρ is the density, A the cross-sectional area, E Young's modulus, I the moment of inertia, and $q(x)$ a distributed applied load. This equation is derived assuming that displacements are small and that sections of the beam normal to the central axis in the unloaded state remain normal during bending; these assumptions are usually valid for small deformations of long, thin beams, although deviations from this linear theory are probable for many applications of CNTs [44,45]. The natural frequency of the i^{th} mode of vibration is then given by

$$\omega_i = \frac{\beta_i^2}{L^2} \sqrt{\frac{EI}{\rho A}} \quad (2)$$

where β_i is the root of an equation that is dictated by the boundary conditions. For a beam clamped at one end (zero displacement and zero slope) and free at the other (zero reaction forces), this equation is

$$\cos \beta_i \cosh \beta_i + 1 = 0 \quad (3)$$

Thus, the frequencies of the first three modes of vibration of a clamped-free beam can be computed from Eq. (3) with $\beta_1 \approx 1.875$, $\beta_2 \approx 4.694$, and $\beta_3 \approx 7.855$.

Measurements on vibrating CNTs can, therefore, be used to estimate Young's modulus. The first experimental measurements of Young's modulus in MWCNTs were made by Treacy *et al* [31], who used a vibrating beam model of a MWCNT to estimate a modulus of about 1.8 TPa. The authors observed TEM images of MWCNTs that appeared to be undergoing thermal vibration, with a mean-square vibration amplitude that was found to be proportional to temperature. Assuming equipartition of the thermal energy among vibrational modes and a hollow cylinder geometry of the tube allowed Young's modulus to be estimated based on the measured amplitude of vibration at the tip of the tube. The spread in the experimental data is quite large, with modulus values for 11 tubes tested ranging from 0.40 to 4.15 TPa with a mean value of 1.8 TPa; the uncertainty was ± 1.4 TPa. A similar study by Krishnan *et al* [46] of SWCNTs found an average modulus of about 1.3–0.4/+0.6 TPa for 27 SWCNTs.

Rather than relying on estimates of thermal vibrations, Poncharal *et al* [44] used electromechanical excitation as method to probe the resonant frequencies of MWCNTs. For tubes of small diameter (less than about 12 nm), they found frequencies consistent with a Young's modulus in the range of 1 TPa. However, for larger diameters, the bending stiffness was found to decrease by up to an order of magnitude, prompting the authors to distinguish their measured *bending modulus* (in the range 0.1 to 1 TPa) from the true Young's modulus. One hypothesis put forth for the decrease in effective modulus is the appearance of a mode of deformation in which a wavelike distortion or *ripple* forms on the inner arc of the bent MWCNT. This mode of deformation is not accounted for by simple beam theory. Liu *et al* [45] used a combination of finite element analysis (using the elastic constants of graphite) and nonlinear vibration analysis to show that nonlinearity can cause a large reduction in the effective bending modulus. However, Poncharal *et al* reported that there was no evidence of nonlinearity (such as a shift of frequency with varying applied force) in their experimental results, which causes some doubt as to whether a large nonlinear effect such as the rippling mode can explain the decrease in bending modulus with increasing tube diameter. Similar resonance excitation of MWCNTs has recently been realized by Yu *et al* [47] inside scanning electron microscope (SEM) (Fig. 8).

Static models of beam bending can also be used to measure mechanical properties. Wong *et al* [48] measured the bending force of MWCNTs using atomic force microscopy (AFM). Assuming the end displacement of an end-loaded cantilevered beam is given by $PL^3/3EI$ where P is the applied force, they fit a Young's modulus of 1.28 ± 0.59 TPa. Salvetat *et al* [49,50] measured the vertical deflection versus the applied force dependence of MWCNTs and SWCNT ropes spanning one of the pores in a well-polished alumina *nanopore* membrane using AFM. They fit values of about 1 TPa for MWCNTs grown by arc discharge, whereas those grown by the catalytic decomposition of hydrocarbons had a modulus 1–2 order of magnitude smaller.

Govinjee and Sackman [51] studied the validity of mod-

eling MWCNTs with Euler beam theory. They showed the size dependency of the material properties at the nanoscale, which does not appear in the classical continuum mechanics. The beam assumption was further explored by Harik [52,53]. From scaling analysis, he proposed three non-dimensional parameters to check the validity of the continuum assumption. The relation between these parameters and MD simulation was discussed. Ru [54–59] has used a shell model to examine the effects of interlayer forces on the buckling and bending of CNTs. It is found that for MWCNTs, the critical axial strain is decreased from that of a SWCNT of the same outside diameter [54–56], in essence because the van der Waals forces between layers always cause an inward force on some of the tubes. Note that although the critical axial strain is reduced, the critical axial force may be increased due to the increased cross-sectional area. The phenomenon is also seen when the CNT is embedded in an elastic matrix [57,58]. Ru uses a similar analysis to treat the buckling of columns of SWCNTs arranged in a honeycomb pattern [59].

2.2.3 Elastic buckling and local deformation of NT

Experiments have shown a few cases of exceptional tensile strength of carbon nanotubes (see section 2.3). In addition, experiment and theory have addressed structural instability for tubes under compression, bending or torsion. Buckling can occur in both the axial and transversal direction. Buckling can also occur in the whole structure or locally. Analysis based on continuum theory and the roles of interlayer potential are discussed in section 4.2.2.

Yakobson *et al* [37,43] modeled buckling of CNTs under axial compression and used the Brenner potential in their MD simulation. Their simulation also showed four *snap-throughs* during the load process, resulting from instability. The first buckling pattern starts at a nominal compressive strain of 0.05. Buckling due to bending and torsion was demonstrated in [37,60–62]. In the case of bending, the pattern is characterized by the collapse of the cross-section in the middle of the tube, which confirms the experimental observations by Iijima *et al* [63] and Ruoff *et al* [64,65] using HRTEM and by Wong *et al* [48] using AFM. When the tube

Fig. 8 Scanning electron microscope (SEM) images of electric field induced resonance of an individual MWCNT at its fundamental resonance frequency (a) and at its second order harmonic (b)

is under torsion, flattening of the tube, or equivalently a collapse of the cross-section, can occur due to the torsional load. Shown in Fig. 9 are the simulation results of buckling patterns using a molecular dynamics simulation code developed by the authors. Falvo *et al* [66] bent MWCNTs by using the tip of an AFM. They showed that MWCNTs could be bent repeatedly through large angles without causing any apparent fracture in the tube. Similar methods were used by Hertel *et al* [67] to buckle MWCNTs due to large bending. Lourie *et al* [68] captured the buckling of SWCNTs under compression and bending by embedding them into a polymeric film. Unlike the single kink seen by Iijima *et al* [63], the buckling pattern under bending was characterized by a set of local rippling modes.

The radial deformability for tubes has also been studied. Ruoff *et al* [69] first studied radial deformation between adjacent nanotubes (Fig. 10). Partial flattening due to van der Waals forces was observed in TEM images of two adjacent and aligned MWCNTs along the contact region. This was the first observation that CNTs are not necessarily perfectly cylindrical. Indeed, in an anisotropic physical environment, all CNTs are likely to be, at least to some degree, not perfectly cylindrical due to mechanical deformation. Tersoff and Ruoff [70] studied the deformation pattern of SWCNTs in a closest-packed crystal and concluded that rigid tubes with diameters smaller than 1 nm are less affected by the van der Waals attraction and hardly deform. But for diameters over 2.5 nm, the tubes flatten against each other and form a honeycomb-like structure. This flattening of larger diameter SWCNTs could have a profound effect on factors such as storage of molecular hydrogen in SWCNT crystals comprised of such larger diameter tubes, if they can be made, because the interstitial void space is dramatically altered. Lopez *et al* has reported the observation, with HRTEM, of polygonized SWCNTs in contact [71].

Chopra *et al* [72] observed fully collapsed MWCNTs with TEM and showed that the collapsed state can be energetically favorable for certain types of CNTs having a certain critical radius and overall wall thickness. Benedicts *et al* [73] proposed the use of the ratio of mean curvature modulus to the interwall attraction of graphite to predict whether the cross-section will collapse or not and applied their model for a collapsed MWCNT observed in TEM by the same authors. In addition, their experiment also provided the first microscopic measurement of the intensity of the inter-shell attraction.

Hertel *et al* [74] and Avouris *et al* [75] studied the van der

Fig. 9 (a) Buckling of SWCNT under bending load, (b) Buckling of SWCNT under torsional load

Waals interaction between MWCNTs and a substrate by both experiment (using AFM) and simulation. They found that radial and axial deformations of the tube may lead to a high energy binding state, depending on the types of CNTs present. Fully or partially collapsed MWCNTs on surfaces have also been reported by Yu *et al* [76,77] and their work included a careful analysis of the mechanics of tubes when in contact with surfaces. Lordi and Yao [78] simulated the radial deformation of CNTs due to a local contact and compared the model structures with experimental images of CNTs in contact with nano-particles. With simulation of both SWCNT and MWCNT up to the radius of a (20, 20) nanotube (13.6 Å), no collapse due to local contact was reported. Instead, the radial deformation was found to be reversible and elastic. Based on these results, they suggested that mechanically cutting a nanotube should be rather difficult, if not impossible.

Gao *et al* [36] carried out an energetics analysis on a wide range of nanotubes. They showed the dependence of geometry on the radius of the tube. To be more specific, a circular cross section is the stable configuration for a radius below 1 nm, in line with the prior results obtained by Tersoff and Ruoff [70] mentioned above. If the radius is between 1 and 2 nm, both circular and collapsed forms are possible. Beyond 3 nm the SWCNT tends to take the collapsed form. However, we should note that the treatment by Gao *et al* is of isolated SWCNTs, and their results would be modified by contact with a surface (which might accelerate collapse, Yu *et al* [76,77]); on the other hand, as already demonstrated by Ter-

Fig. 10 Left: HRTEM image of two adjacent MWCNTs *a* and *b* [69]. Nanotube *a* has 10 fringes and Nanotube *b* has 12 fringes. The average interlayer spacing for inner layers and outer layers belonging to the MWCNT *a* are 0.338 nm and 0.345 nm, respectively. For MWCNT *b*, these are 0.343 nm and 0.351 nm, respectively. This 0.07 and 0.08 nm differences are due to the compressive force acting in the contact region, and the deformation from perfectly cylindrical shells occurring in both inner and outer portions of each MWCNT. Right, from top to bottom: (a) Calculated deformation resulting from van der Waals forces between two double layered nanotubes. (b) Projected atom density from (a). The projected atom density is clearly higher in the contact region, in agreement with the experimental observation of the much darker fringes in the contact region as compared to the outer portions of MWCNTs *a* and *b*. (c) Calculated deformation for adjacent single layer nanotubes (from [69]).

soff and Ruoff [70], completely surrounding a SWCNT by similar sized SWCNTs might stabilize against complete collapse.

It is interesting to speculate whether larger diameter SWCNTs would *ever* remain completely cylindrical in any environment. A nearly isotropic environment would be a liquid comprised of small molecules, or perhaps a *homogeneous* polymer comprised of relatively small monomers. However, because the CNTs have such small diameters, fluctuations are present in the environment on this length scale, locally destroying the time-averaged isotropicity present at longer length scales, may trigger collapse. Alternatively, if full collapse does not occur, the time-averaged state of such a CNT in a (time-averaged) isotropic environment might be perfectly cylindrical. Perhaps for this reason, CNTs might be capable of acting as probes of minute fluctuations in their surrounding (molecular) environment.

Shen *et al* [79] conducted a *radial* indentation test of ~ 10 nm diameter MWCNTs with scanning probe microscopy. They observed deformability (up to 46%) of the tube and resilience to a significant compressive load ($20 \mu\text{N}$). The radial compressive elastic modulus was found to be a function of compressive ratios and ranged from 9.0 to 80.0 GPa.

Yu *et al* [80] performed a nano-indentation study by ap-

Fig. 11 Deformability of a MWCNT deposited on a patterned silicon wafer as visualized with tapping-mode AFM operated far below mechanical resonance of a cantilever at different set points. The height in this and all subsequent images was coded in gray scale, with darker tones corresponding to lower features. (a) Large-area view of a MWCNT bent upon deposition into a hairpin shape. (b)–(e) Height profiles taken along the thin marked line in (a) from images acquired at different set-point (S/S_0) values: (b) 1.0; (c) 0.7; (d) 0.5; (e) 1.0. (f)–(i) Three-dimensional images of the curved region of the MWCNT acquired at the corresponding set-point values as in (b)–(e). (from [80]).

plying compressive force on individual MWCNTs with the tip of an AFM cantilever in tapping-mode (Fig. 11) and demonstrated a deformability similar to that observed by Shen *et al.* They estimated the *effective* elastic modulus of a range of indented MWCNTs to be from 0.3 GPa to 4 GPa by using the Hertzian contact model. The reader should note that the difference between this effective elastic modulus and the elastic modulus discussed in Section 2.2.1 is that the effective modulus refers to the elastic response to deformation of an anisotropic indentation load applied in the radial direction. We thus also distinguish this type of load from the *isotropic* load that could, eg, be applied by high pressure for CNTs suspended in a liquid pressure medium, which is more appropriately referred to as *isotropic radial compressive loading*. Yu *et al* [77] provided further energetics analysis on

Fig. 12 A freestanding twisted MWCNT ribbon. (a) A TEM image of this ribbon anchored on one end by a carbon support film on a lacy carbon grid. Arrows point to the twists in the ribbon. (b) and (c) 8 resolved fringes along both edges of the ribbon imaged near the anchor point. (d) A schematic depicting the AB stacking between armchair CNT shells (the two layers are: the layer having brighter background and black lattices versus the layer having darker background and white lattices). The AB stacking can be achieved by just shifting the layer positions along the x direction that is perpendicular to the long axis of the MWCNT. (e) A schematic depicting the lattice alignment between the zigzag CNT shells by allowing the relative shifting of the layers along x direction. The AB stacking is not possible and only AA stacking or other stacking (as shown in the schematic) is possible (from [83]).

MWCNTs that are in configurations of partial or full collapse, or collapsed combined with a twist. They showed that interlayer van der Waals interactions play an important role in maintaining the collapsed configuration.

Chesnokov *et al* [81] observed remarkable reversible volume compression of SWCNTs under quasi-hydrostatic pressure up to 3 GPa and obtained a volume compressibility of 0.0277 GPa^{-1} , which suggests the use of CNT as energy-absorbing materials. The volume compressibility of SWCNTs having a diameter of 1.4 nm under hydrostatic pressure was also studied by Tang *et al* [82] by *in situ* synchrotron x-ray diffraction. The studied SWCNT sample, which consisted primarily of SWCNT bundles and thus not individual or separated SWCNTs, showed linear elasticity under hydrostatic pressure up to 1.5 GPa at room temperature with a compressibility value of 0.024 GPa^{-1} , which is smaller than that of graphite (0.028 GPa^{-1}). However, the lattice structure of the SWCNT bundles became unstable for pressure beyond $\sim 4 \text{ GPa}$, and was destroyed upon further increasing the pressure to 5 GPa.

A very subtle point that comes into the picture is the effect of interlayer interactions when CNTs collapse. This effect can produce some results that cannot be described by traditional mechanics. For instance, Yu *et al* [83] observed fully collapsed MWCNT ribbons in the twisted configuration with TEM. One such cantilevered MWCNT ribbon had a twist present in the freestanding segment (Fig. 12a). Such a configuration cannot be accounted for by elastic theory since no external load (torque) is present to hold the MWCNT ribbon in place and in the twisted form. However, it is known that a difference of approximately 0.012 eV/atom in the interlayer binding energy of the AA and the AB stacking configurations (Fig. 12d and c) exists for two rigid graphitic layers spaced 0.344 nm apart. The analysis by Yu *et al* [83] suggests that the elastic energy cost for the twist formation of this particular CNT ribbon can be partially compensated by achieving more favorable atomic registry. The observation of the existence of this freestanding twist in the ribbon thus suggests that an energy barrier exists to keep the twisted ribbon from untwisting. The mechanics analysis performed suggests that this twisted structure is metastable. More details on the modeling of interlayer interaction with the account of this registry effect are presented in 4.2.2.

As a brief summary, compared with their high rigidity in the axial direction, CNTs are observed to be much more compliant in the radial direction. Thus a CNT readily takes the form of a partially or fully collapsed *nano-ribbon* when the radius and wall thickness are in particular ranges, when either isolated in free space or in contact with a surface. A CNT may also locally flatten when surrounded, as for example occurs in the SWCNT bundles.

2.3 Strength of nanotubes

The strength of a CNT will likely depend largely on the distribution of defects and geometric factors. In the case of geometric factors, buckling due to compression, bending and torsion has been discussed in Section 2.2.3. Note that even in

these loading cases, it is still possible for plastic yielding to take place due to highly concentrated compressive force. Another geometric factor is the interlayer interaction in the case of MWCNTs and bundles of CNTs.

2.3.1 Strength due to bond breaking or plastic yielding

Unlike bulk materials, the density of the defects in nanotubes is presumably less and therefore the strength is presumably significantly higher at the nanoscale. The strength of the CNT could approach the theoretical limit depending on the synthesis process. There are several major categories of synthesis method: carbon evaporation by arc current discharge [1,84,85] or laser ablation [86,87], or chemical vapor deposition (CVD) [86–90]. MWCNTs produced by the carbon plasma vapor processes typically possess higher quality in terms of defects than those produced by the shorter time, lower temperature CVD processes. However, it is not known at this time whether the SWCNTs produced, for example, by the laser ablation method, are better than those produced by CVD growth from pre-formed metal catalyst particles present on surfaces. It is thus worth mentioning the essential role of various catalysts in the production of SWCNTs [91].

There have been few experimental reports on testing the tensile strength of nanotubes. The idea is simple, but seems rather difficult to implement at this stage. Yu *et al* [28] were able to apply a tensile load on 15 separate SWCNT bundles and measure the mechanical response (Fig. 13). The maximum tensile strain they obtained was 5.3%, which is close to the theoretical prediction made by Nardelli *et al* [92]. The *average* SWCNT tensile strength for each bundle ranged from 13 to 52 GPa, and was calculated by assuming the load was applied primarily on the SWCNTs present at the perimeter of each bundle.

Tensile loading of 19 individual MWCNTs was reported by Yu *et al* [29] (Fig. 14) and it was found that the MWCNTs broke in the outermost layer by a *sword-in-sheath* breaking

Fig. 13 SEM image of a tensile loaded SWCNT bundle between an AFM tip and a SWCNT *buckytube paper* sample (from [28])

mechanism with tensile strain at break of up to 12%. The tensile strength of this outermost layer (equivalent to a large diameter SWCNT) ranged from 11 to 63 GPa.

By laterally stretching suspended SWCNT bundles fixed at both ends using an AFM operated in lateral force mode, Walters *et al* [93] were able to determine the maximum elongation of the bundle, and thus the breaking strain. The tensile strength was thus estimated to be 45 ± 7 GPa by assuming a Young's modulus of 1.25 TPa for SWCNT. The tensile strength of very long (~ 2 mm) ropes of CVD-grown aligned MWCNTs was measured to be 1.72 ± 0.64 GPa by Pan *et al* [94] using a modified tensile testing apparatus, by constantly monitoring the resistance change of the ropes while applying the tensile load. The much lower value they obtained is perhaps to be expected for CVD-grown MWCNTs, according to the authors. But another factor may be the much longer lengths tested, in that a much longer CNT may be more likely to have a critical concentration of defects that could lead to failure present somewhere along their length. The dependence of fracture strength on length has not yet been experimentally addressed.

Another way of applying tensile load is to use the load transferred by embedding the CNTs in a matrix material. Wagner *et al* [95] observed fragmentation in SWCNTs using this method and reported a tensile strength of 55 GPa. Tensile strength measurements on a resin-based SWCNT composite were performed by Li *et al* [96]. Through a treatment that includes modeling the interfacial load transfer in the SWCNT-polymer composite the tensile strength of the SWCNTs was fit to an average value of ~ 22 GPa. A compression test of the CNT has been performed by Lourie *et al* [68] in which in addition to the buckling mode that is mentioned in section 2.2.3, they also observed plastic collapse and fracture of thin MWCNTs. The compressive strength and strain corresponding to these cases were estimated to be approximately 100–150 GPa and $>5\%$, respectively.

Theoretical prediction of CNT strength has emphasized the roles of defects, loading rate, and temperature using MD simulation. Yakobson *et al* [37,43,61,97] performed a set of MD simulations on the tensile loading of nanotubes. Even with very high strain rate, nanotubes did not break com-

pletely in half, and the two separated parts were instead connected by a chain of atoms. The strain and strength from these simulations are reported to be 30% and 150 GPa, respectively. The fracture behavior of CNT has also been studied by Belytschko *et al* [98] using MD simulations. Their results show moderate dependence of fracture strength on chirality (ranges from 93.5 GPa to 112 GPa) and fracture strain between 15.8% and 18.7% were reported. In these simulations, the fracture behavior is found to be almost independent of the separation energy and to depend primarily on the inflection point in the interatomic potential. The values of fracture strains compare well with experimental results by Yu *et al* [29].

A central theme that has been uncovered by quantum molecular dynamics simulations of plastic yielding in CNTs is the effect of pentagon/heptagon (or 5/7) defects (see Fig. 15, where the bond rotation leading to the 5-7-7-5 defect initially formed, is referred to as the *Stone-Wales bond-rotation* [8]) which for certain types of SWCNTs and at sufficiently high temperature can lead to plastic yielding ([97]). Nardelli *et al* [100] studied the mechanism of strain release under tensile loading using both classical and quantum molecular dynamics (MD and QMD). They found that in the case of tension, topological defects such as the 5-7-7-5 defect tend to form when strain is greater than 5% in order to achieve the relaxation of the structure. At high temperature (which for these carbon systems means temperatures around 2000 K) the 5-7-7-5 defect can, for a subset of the SWCNT types, separate into two 5,7 pairs that can glide with respect to each other. Nardelli *et al* [92] observed the ductile-to-brittle failure transition as a function of both temperature and strain in their MD simulation. Generally, high strain (15%) and low temperature (1300 K) lead to brittle behavior (crack extension or separation), while low strain (3%) and high temperature

Fig. 14 Tensile loading of individual MWCNTs. (a) An SEM image of a MWCNT attached between two AFM tips. (b) Large magnification image of the indicated region in (a) showing the MWCNT between the AFM tips (Reprinted with permission from [29]. Fig. 15 The “5-7-7-5” dislocation evolves as either a crack (brittle cleavage), or as a couple of dislocations gliding away along the spiral *slip plane* (plastic yield). In the latter case, the change of the nanotube chirality is reflected by a stepwise change of diameter and by corresponding variations of electrical properties (Reprinted from [99] with permission from Elsevier Science).

(3000 K) make nanotubes more ductile (dislocation motion without cracking). The reader is reminded of the short time scale of these simulations.

Srivastava *et al* [101] demonstrated that a local reconstruction leading to formation of sp^3 bonds can occur under compressive load, and obtained a compressive strength of approximately 153 GPa. Wei *et al* [102] and Srivastava *et al* [103] demonstrated that finite temperature (starting from 300 K) can help the nanotube to overcome a certain energy barrier to achieve plastic deformation. They conducted a similar study of the temperature effect using MD with compressive loading at 12% strain and observed both the formation of sp^3 bonds (at 300 K) and 5/7 defects (1600 K) for an (8,0) tube. In addition, it was reported [103] that a slower strain rate tends to trigger plastic yield. The conclusion is very similar to the one obtained by Nardelli *et al* [100], but a subtle question is whether the ductile behavior is due to strain or strain rate.

A detailed analysis on the mechanism of defects and dislocation is presented by Yakobson [61,104]. It was shown that the glide direction of the 5/7 defects is dependent on the chirality of the nanotube and consequently an irreversible change in the electronic structure also takes place in the vicinity of the chirality change (an armchair tube changes from metallic to semiconducting). Similar conclusions about the effect of strain release on the electronic structure of the tube have been given by Zhang *et al* [105]. Zhang *et al* also observed the dependence of the elastic limit (the onset of plastic yielding) on the chirality of the tube: for the same radius, an $(n,0)$, thus zigzag, tube has nearly twice the limit of an (n,n) , thus armchair, tube. This is due mostly to the different alignment of the defects with the principle shear direction. The compressive strength they obtained ranged from 100 to 170 GPa. Another mechanism of defect nucleation is described by Zhang and Crespi [106] where plastic flow can also occur due to the spontaneous opening of double-layered graphitic patches.

As a brief summary, experimental and simulation efforts have recently been undertaken to assess the strength of CNT. A major limitation for simulation currently is the small time scale that current MD methods can address, much shorter than are actually implemented in experiment. This issue is dealt within [103]. Implicit methods and bridging scale methods show promise in alleviating this difficulty.

2.3.2 Strength due to interlayer sliding

Most synthesized nanotubes are either randomly agglomerated MWCNTs or bundles of closest-packed SWCNTs [85,90]. The SWCNTs have a narrow diameter distribution as synthesized, and are consequently typically tightly and efficiently packed in bundles [87,107]. The tensile response of SWCNT nanoropes has been measured by Yu *et al* [28]; tensile loading of individual MWCNTs was presented by Yu *et al* [29]. They demonstrated that MWCNTs that are mounted by attachment to the outermost shell and then loaded in tension break in the outermost shell thus indicating negligible load transfer to the inner shells. This limits the potential of MWCNTs for structural applications—in terms

of exhibiting high stiffness and strength in tension, they are a victim of their own high perfection of bonding as there is evidently no covalent bonding between the nested shells and thus little or no load transfer from the outer shell to the inner shells.

The weak inter-shell interaction has been measured by Yu *et al* [11] (Fig. 16) and estimated by Cumings and Zettl [108]. In the study of *shell-sliding* of two MWCNTs by Yu *et al* [11], direct measurement of the dependence of the pulling force on the contact length between the shells was performed, and the shear strength between the outermost shell and the neighboring inner shell for two MWCNTs was found to be 0.08 and 0.3 MPa, respectively. These values are on the low end of the experimental values of the shear strength in graphite samples [109], thus emphasizing the weak inter-shell interactions in *high quality, highly crystalline* MWCNTs, similar to the type originally discovered by Iijima [1]. Cumings *et al* [108] demonstrated inside a TEM that a *telescope process* can be repeated on the MWCNTs that they tested up to 20 times without causing any apparent damage. (The reader should note that assessment of damage at the nanoscale is quite challenging. Here, the authors simply note that there was no apparent change as imaged by high resolution TEM.) These two studies motivate pondering the possibility of a nanoscale bearing system of exceptional quality. The shear strengths corresponding to static friction and dynamic friction were estimated to be 0.66 and 0.43 MPa, respectively [108]. These values are on the same order as what Yu *et al* obtained by experimental measurement [11].

For SWCNT bundles, there have been theoretical estimates that in order to achieve load transfer so that the full bundle cross-section would be participating in bearing load

Fig. 16 The forces involved in the shell-sliding experiment can be described by $F_a = F_s + F_i = \pi d \tau L(t) + F_i$, where F_a is the applied pulling force as a function of time, τ is the shear strength, L is the contact length, d the shell diameter, and F_i is a diameter dependent force originating from both surface tension and *edge effects*. SEM images showing the sword-in-sheath breaking mechanism of MWCNTs: (a) A MWCNT attached between AFM tips under no tensile load, (b) The same MWCNT after being tensile loaded to break. Notice the apparent overall length change of the MWCNT fragments after break compared to the initial length and the curling of the top MWCNT fragment in (b) (from [11]).

up to the intrinsic SWCNT breaking strength (when loading has, for example, been applied only to those SWCNTs on the perimeter), the SWCNT contact length must be on the order of 10 to 120 microns [110,111]. This is much longer than the typical length of individual SWCNTs in such bundles [112,113], where mean length values on the order of a few hundred nanometers have been obtained. This means that load transfer in a parallel bundle containing such relatively short SWCNTs is very likely to be very small and thus ineffective. Quantitative analysis of actual dynamics by modeling using MD requires an interlayer potential that precisely accounts for the interlayer interaction as a function of relative slide position as well as correct incorporation of thermal effects. A general discussion of interlayer potentials is presented in Section 3.2.2.

2.4 Elastic properties based on crystal elasticity

It now can be seen that all the theoretical studies presented in Section 2.2.1 have either failed to distinguish between the case of infinitesimal strain and finite strain or have directly applied the result at infinitesimal strain to the case of finite strain. In this section, the elastic properties of CNTs at finite strain will be discussed. The significance of this study is obvious from the various deformation patterns due to the load. Of particular interest is the derivation of the elastic constants based on a known atomic model, from either an empirical expression or *ab initio* calculation.

Early attempts to derive elastic constants based on the potential energy of a crystal system were made by Born and Huang [114]. In their treatment, the potential energy was expressed as a function of the displacements of atoms. Since the formulation does not generally guarantee the rotational invariance, the so-called Born-Huang conditions were proposed. Keating [115–118] showed the inconsistencies in the Born-Huang conditions and stated that the potential energy of the crystal system can be alternately expressed in terms of the variables that intrinsically preserve the invariance property. Based on Brugger's thermodynamic definition [119] of elastic constants, Martin [120–122] derived elastic constants for a crystal system in which the energy density is a sum of the contributions from many-body interactions. Martin's approach is in fact a hyperelastic approach since the energy density was considered as a function of the Lagrangian strain. Based on the Embedded-Atom Method (EAM) [123,124], Tadmor *et al* [125,126] derived the corresponding elasticity tensor at finite deformation in their quasicontinuum analysis. Friesecke and James [127] proposed another approach of bridging between continuum and atomic structure, with emphasis on nano-structures in which the size of one dimension is much larger than the other.

The essence of hyperelasticity has been discussed in detail in [128–130]. The advantage of the hyperelastic formulation is that it is inherently material frame-invariant; therefore, no special treatment is needed in the large deformation computation.

As a brief summary, if the energy density W of the mate-

rial is known, the relation between the nominal stress \mathbf{P} and the deformation gradient \mathbf{F} is given as (see Belytschko, Liu, and Moran [128])

$$\mathbf{P} = \frac{\partial \mathbf{W}}{\partial \mathbf{F}^T} \quad \text{or} \quad P_{ij} = \frac{\partial W}{\partial F_{ji}} \quad (4)$$

In (4), $F_{ij} = \partial x_i / \partial X_j$, in which x and X are respectively the spatial and material coordinates. The lower case subscript denotes the dimension. An equivalent form is to express in terms of the 2nd Piola-Kirchhoff stress \mathbf{S} (referred to as 2nd PK stress) and Lagrangian strain \mathbf{E} , ie,

$$\mathbf{S} = \frac{\partial \mathbf{W}}{\partial \mathbf{E}} \quad \text{or} \quad S_{ij} = \frac{\partial W}{\partial E_{ij}} \quad (5)$$

Correspondingly, there are two sets of elasticity tensors:

$$\mathbf{C}^{PF} = \frac{\partial^2 \mathbf{W}}{\partial \mathbf{F}^T \partial \mathbf{F}^T} \quad \text{or} \quad C_{ijkl}^{PF} = \frac{\partial^2 W}{\partial F_{ji} \partial F_{lk}} \quad (6)$$

and

$$\mathbf{C}^{SE} = \frac{\partial^2 \mathbf{W}}{\partial \mathbf{E} \partial \mathbf{E}} \quad \text{or} \quad C_{ijkl}^{SE} = \frac{\partial^2 W}{\partial E_{ij} \partial E_{kl}} \quad (7)$$

\mathbf{C}^{PF} and \mathbf{C}^{SE} are generally referred to as the *first elasticity tensor* and the *second elasticity tensor*, respectively. Their difference is mainly governed by different stress and strain measures that are involved in their definition. It can be shown that the two elasticity tensors are related by

$$C_{ijkl}^{PF} = C_{imnk}^{SE} F_{jm} F_{ln} + S_{ik} \delta_{lj} \quad (8)$$

where δ_{ij} is the Kronecker delta.

In addition, there are also the *third elasticity tensor* $C_{ijkl}^{(3)}$ and *fourth elasticity tensor* $C_{ijkl}^{(4)}$. The *third elasticity tensor* relates the velocity gradient $L_{ij} = \partial v_i / \partial x_j$ to the push-forward of the rate of nominal stress \mathbf{P} , ie,

$$F_{ir} \dot{P}_{rj} = C_{ijkl}^{(3)} L_{kl}^T \quad (9)$$

The fourth elasticity tensor is the spatial form of the second elasticity tensor and is defined by

$$C_{ijkl}^{(4)} = F_{im} F_{jn} F_{kp} F_{lq} C_{mnpq}^{SE} \quad (10)$$

It can be shown that the fourth elasticity tensor is essentially the tangent moduli in the spatial form and it relates the convective rate of the Kirchhoff stress to the rate of deformation

$$D_{ij} = \frac{1}{2}(L_{ij} + L_{ji}) \quad (11)$$

The convected rate of Kirchhoff stress corresponds to the mathematical concept of Lie derivatives, which consistently defines the time derivatives of tensors. Therefore, the fourth elasticity tensor plays an important role in maintaining objectivity during stress update and material stability analysis. More detailed descriptions can be found in Chapters 5 and 6 in the book by Belytschko, Liu, and Moran [128].

To apply hyperelasticity to the crystal system, the Cauchy-Born rule [125,131,132] must be imposed. This rule assumes that the local crystal structure deforms homogeneously and that the mapping is characterized by the deformation gradient F . With this assumption, we can apply the

Eqs. (4)–(7) to specific atomic models of the nanotube system. We consider the undeformed state of the CNT to be the same as that of a graphene sheet and adopt the classical Tersoff-Brenner model [35,133–136]. The empirical equation is given as follows

$$\Phi_{ij} = \Phi_R(r_{ij}) - \bar{B}_{ij}\Phi_A(r_{ij}) \quad (12)$$

in which i, j are the indices for carbon atoms. Φ_R and Φ_A represent the repulsive and attractive part of the potential, respectively. The effect of bonding angle is considered in the term \bar{B}_{ij} . The detailed expression for each individual term looks a little tedious due to the consideration of many-body effects. Readers may consult the original paper [35] for parameters and functional forms.

The basic element of the graphite structure is a single hexagon, with each side of the hexagon a result of the covalent bond due to sp^2 hybridization described in Section 2.1.1. Since each bond is also shared by the other neighboring hexagon, the total bonding energy Φ for one hexagon can be given as half of the summation of the bonding energy from all six covalent bonds. This summation can be further reduced if the symmetry is considered. The energy density, due to the fact that the single layer of graphite is only a result of repeating the hexagon structure, is given as

$$W = \frac{\Phi}{A_0} \quad (13)$$

with $\Phi = \sum_{I=1}^3 \Phi_I$. In Eq. (13), A_0 is the area of the undeformed hexagon and Φ_I is the bond energy for the I -th bond. According to Brenner's potential

$$\Phi_I = \Phi_I(r^I, r^{I1}, r^{I2}, \cos \theta^{I1}, \cos \theta^{I2}) \quad (14)$$

in which $I1$ and $I2$ refer to the neighboring bonds of bond I and Φ_I is a function of bond lengths and bonding angles. Note that W is in fact the surface energy density of the system and the thickness term t is not needed because we are dealing with a single layer of graphite. As a result of this, the units for the stress and elasticity tensors are different from those used in the conventional procedures. According to Section 2.1.2, the deformation gradient is determined by the roll-up vector, which is composed of the direction and length of rolling operation, and the subsequent mechanical relaxation after rolling. These effects are embedded in the deformation gradient F_{ij} . The relaxed structure can be obtained from MD simulation for a specific type of CNT. We have evaluated elastic constants and Young's modulus for various types of nanotubes. For the purpose of comparison, we have converted the elastic constants and Young's modulus by assuming an artificial thickness $t=0.34$ nm. With this assumption, the second elasticity tensor in the hyper-elastic formulation is given as

$$C_{ijkl}^{SE} = \frac{\partial S_{ij}}{\partial E_{kl}} \quad (15a)$$

With

$$S_{ij} = \frac{1}{A_0 t} \sum_{I=1}^3 \left(\sum_{N=I, I1, I2} \frac{\partial \Phi_I}{\partial r^N} \frac{\partial r^N}{\partial E_{ij}} + \sum_{N=1,2} \frac{\partial \Phi_I}{\partial \cos \theta_{IN}} \frac{\partial \cos \theta_{IN}}{\partial E_{ij}} \right) \quad (15b)$$

We view the concept of *Young's modulus* as a tangent modulus that is defined in the deformed configuration (the CNT as a result of rolling the graphene sheet). Therefore, it can be calculated from both the above equation and the expression for the fourth elasticity tensor (10). The standard definition of Young's modulus is the ratio of the uniaxial stress exerted on a thin rod (a nanotube in our case) to the resulting normal strain in the same direction. If we define 1 to be the axial direction and 2 and 3 to be the other two orthogonal directions, then it can be shown that the relation between Young's modulus Y and the elastic constants is given as

$$Y = \frac{C_{11}C_{23}^2 + C_{12}C_{13}^2 + C_{33}C_{12}^2 - C_{11}C_{22}C_{33} - 2C_{12}C_{13}C_{23}}{C_{23}^2 - C_{22}C_{33}} \quad (16a)$$

$$C_{ijkl} = F_{im}F_{jn}F_{kp}F_{lq} \left(\frac{\partial S_{mn}}{\partial E_{pq}} \right) \quad (16b)$$

Note that the Voigt notation has been used in Eq. (16a) and elastic constants correspond to the components of the fourth elasticity tensor are defined in Eq. (16b). By plugging the model parameters and the deformation gradient, the Young's modulus for a (10,10) and (100,100) nanotube are obtained as 0.7 and 1TPa, respectively. It is observed that the Young's modulus from the case of (10,10) is quite different from that of graphite due to the effect of rolling. Such effect becomes small as the radius of CNT increases. Note that this value of Young's modulus is determined *consistently* based on crystal elasticity *combined* with the use of MD simulation. In contrast with some of the approaches described in Section 2.2.1 which use purely molecular dynamics to determine the Young's modulus, the approach is semi-analytical and serves as a link between the continuum and atomistic scale. In addition, as we extend to the finite deformation case, the issue of anisotropy naturally arises as a result of this formulation, which can only be qualitatively reproduced by MD. It is emphasized that the thickness assumption is only used in the comparison with the experiments or theoretical predictions that have taken the interlayer separation as the thickness. Clearly, this thickness t is not needed in our formulation.

The procedure described above reveals certain limitations of the standard hyper-elastic approach and Cauchy-Born rule, which can be described as follows

- the deformation is in fact not homogeneous as the graphene sheet is rolled into CNT. Correspondingly the energy of the CNT not only depends on the deformation gradient, but also depends on higher order derivatives of F . In such case, a set of high-order elastic constants that belongs to the framework of *multipolar* theory [137] needs to be determined.
- Another aspect that has been missing in the hyperelastic

theory is the dependence of the energy on the so-called inner-displacement of the lattice, which can be defined as the relative displacement between two overlapping Bravais lattices. Note that the inner displacement can occur without violating the Cauchy-Born rule. According to Cousins [138], the consideration of these variables results in the so-called *inner elastic constants*.

In general, the factors mentioned above are difficult to evaluate through purely analytical methods. A continuum treatment which accounts for the effect of inner displacement has been proposed recently in [139–141]. For computational implementations, see Section 4.3.

3 EXPERIMENTAL TECHNIQUES

The extremely small dimensions of CNTs, diameters of a few tens of nanometers for MWCNTs and about 1 nm for SWCNTs, and length of a few microns, impose a tremendous challenge for experimental study of mechanical properties. The general requirements for such study include *i*) the challenge of CNT placement in an appropriate testing configuration, such as of picking and placing, and in certain cases the fabrication of clamps; *ii*) the achievement of desired loading; and *iii*) characterizing and measuring the mechanical deformation at the nanometer length scale. Various types of high-resolution microscopes are indispensable instruments for the characterization of nanomaterials, and recent innovative developments in the new area of *nanomanipulation* based on inserting new tools into such instruments have enhanced our ability to probe nanoscale objects. We discuss several of these below.

3.1 Instruments for the mechanical study of carbon nanotubes

Electron microscopy (EM, SEM, and TEM) and scanning probe microscopy (SPM) have been the most widely used methods for resolving and characterizing nanoscale objects. Electron microscopy uses high-energy electron beams (several keV up to several hundred keV) for scattering and diffraction, which allows the achievement of high resolving power, including down to sub-nanometer resolution because of the extremely short wavelength (a fraction of an Angstrom) of electrons at high kinetic energy.

We and others have primarily used transmission electron microscopy (TEM) and scanning electron microscopy (SEM) to study nanotube mechanics. In TEM, an accelerated electron beam from a thermal or a field emitter is used. The beam transmits through the sample, passes several stages of electromagnetic lenses, and projects the image of the studied sample region to a phosphor screen or other image recording media. In SEM, a focused electron beam (nanometers in spot size) is rastered across the sample surface and the amplified image of the sample surface is formed by recording the secondary electron signal or the back scattering signal generated from the sample.

Sample requirements typically differ between TEM and SEM. In TEM, a thin (normally several tens of nanometers or less in thickness) and small (no more than 50 mm²) sample is required since a small sample chamber is available

and a dedicated holder is typically used in these expensive instruments (which are thus typically time-shared among many users) for sample transfer. In SEM, there is no strict limit on sample size in principle, and normally a large sample chamber is available so that samples can be surveyed over large areas. As to the difference in the ultimate resolution, TEM is limited by such factors as the spread in energy of the electron beam and the quality of the ion optics, and SEM is limited by the scattering volume of the electrons interacting with the sample material. TEM normally has a resolution on the order of 0.2 nm while SEM is capable of achieving a resolution up to 1 nm.

An exciting new development in electron microscopy is the addition of aberration correction, also referred to as *corrective ion optics*. We provide no extensive review of this topic here, but note for the reader that a coming *revolution* in electron microscopy will allow for image resolution of approximately 0.04 nm with TEM, and of about 0.1 nm for SEM, and perhaps better. There are two types of corrective ion optics, one corrects for spherical aberration (to correct for aberration in the lenses) and one for achromatic aberration (meant to correct for the spread in the wavelengths of the electrons emanating from the emitter). As newer instruments are installed in the next few years, such as, at national laboratories, improvement in the image resolution for mechanics studies of nano-sized specimens is an enticing goal (see, for example, <http://www.ornl.gov/reporter/no22/dec00.htm> and <http://www.nion.com/>).

The scanning, or atomic force, microscope (SFM also referred to as AFM) has also been particularly useful for mechanical studies of CNTs. Since the invention of the AFM in 1986 [143], it has been quickly accepted as a standard tool for many applications related to surface characterization. High-resolution (nanometer up to atomic resolution) mapping of surface morphology on almost any type of either conductive or nonconductive material can be achieved with an SFM.

The principle of the microscope is relatively simple. A probe having a force sensitive cantilever with a sharp tip is used as a sensor to physically scan, in close proximity to, the sample surface. The probe is driven by a piezoelectric tube capable of nanometer resolution translations in the *x*, *y* and *z* directions, and the tip normally has a radius of curvature on the order of 10 nm. The force interaction between tip and sample results in deflection of the cantilever. While scanning the sample surface in the *x* and *y* directions, the deflection of the cantilever is constantly monitored by a simple optical method or other approaches. A feedback electronic circuit that reads the deflection signal and controls the piezoelectric tube is responsible for keeping a constant force between the tip and the sample surface, and a surface profile of the sample can thus be obtained. Depending on the type of interaction force involved for sensing, an SPM instrument can include a host of methods, such as AFM, friction force microscopy (FFM), magnetic force microscopy (MFM), electric force microscopy (EFM), and so on. Depending on the mechanism used for measuring the force interaction, scanning probe microscopy also includes many modes of opera-

tion, such as contact mode, tapping mode, force modulation-mode, and so on. For more information on scanning force microscopy, see for example [142,143] and <http://www.thermomicro.com/spmguide/contents.htm>.

3.2 Methods and tools for mechanical measurement

In the following, a brief summary of the methods used to date for measuring the mechanical properties of CNTs, and especially isolated individual CNTs will be presented, and new tools specifically designed for such tasks will be introduced.

3.2.1 Mechanical resonance method

Treacy and co-workers [31] deduced values for Young's modulus for a set of MWCNTs by measuring the amplitude from recorded TEM images of the thermal vibration of the free ends of each when naturally cantilevered. Krishnan *et al* [46] succeeded in measuring the Young's modulus of SWCNTs (Fig. 17), using a similar method. The amplitude was measured from the blurred spread of tip positions of the free end of the cantilevered CNT compared to the clamped end. The amplitude can be modeled by considering the excitation of mechanical resonance of a cantilever:

$$\sigma^2 = \frac{16L^3kT}{\pi Y(a^4 - b^4)} \sum_n \beta_n^{-4} \approx 0.4243 \frac{L^3kT}{Y(a^4 - b^4)} \quad (17)$$

Fig. 17 TEM images of vibrating single-walled nanotubes. Inserted with each micrograph is the simulated image corresponding to the best least-square fit for the adjusted length L and tip vibration amplitude σ . The tick marks in each micrograph indicate the section of the nanotube shank that was fitted. The nanotube length, diameter W , tip amplitude and the estimated Young's modulus E , are (a) $L=36.8$ nm, $\sigma=0.33$ nm, $W=1.50$ nm, $E=1.33 \pm 0.2$ TPa; (b) $L=24.3$ nm, $\sigma=0.18$ nm, $W=1.52$ nm, $E=1.20 \pm 0.2$ TPa; and (c) $L=23.4$ nm, $\sigma=50.30$ nm, $W=1.12$ nm, $E=1.02 \pm 0.3$ TPa (from [46]).

where σ is the amplitude at the free end, L is the length of the cantilevered beam, k is the Boltzman constant, T is the temperature, Y is the Young's modulus, a is the outer radius and b is the inner radius of CNT, and β_n is a constant for free vibration mode n . The tip blurring originates from thermal activation of vibrations (the CNT behaves classically because of the low frequency modes that are populated by the expected kT of thermal vibrational energy), and the amplitude can be modeled by considering the excitation of mechanical resonance of a cantilever. The image is blurred simply because the frequency is high relative to the several second integration time needed for generating the TEM image. Since the resonance is a function of the cantilever stiffness, and the geometry is directly determined by the TEM imaging, the Young's modulus values could be fit. The advantage of this method is that it is simple to implement without the need for additional instrument modification or development—only a variable-temperature TEM holder is needed. The principle can also be applied for the study of other nanowire-type materials as long as the tip blurring effect is obvious. The drawback is that a model fit is needed to determine the real cantilever length, and human error is inevitable in determining the exact amplitude of the blurred

Fig. 18 Electric field driven resonance of MWCNT: (a) In the absence of a potential, the nanotube tip ($L=6.25$ nm, $D=14.5$ nm) vibrated slightly because of thermal effects; (b) Resonant excitation of the fundamental mode of vibration ($f_1=530$ kHz); (c) Resonant excitation of the second harmonic ($f_2=3.01$ MHz). For this nanotube, a value of $E_b=0.21$ TPa was fit to the standard continuum beam mechanics formula (Reprinted with permission from [44]. tip. As pointed out by the authors, the error for the Young's modulus estimation using such method is around $\pm 60\%$.

Poncharal *et al* [44] introduced an electric field excitation method (Fig. 18) for the study of mechanical resonance of cantilevered MWCNTs, and measured the bending modulus. In the experiment, a specially designed TEM holder, which incorporated a piezo-driven translation stage and a mechanical driven translation stage, was developed. The translation stages allowed the accurate positioning of the MWCNT material inside the TEM, in this case relative to a counter electrode. Electrical connections were made to the counter electrode and the electrode attaching the MWCNT materials, so that DC bias as well as AC sinusoidal voltage could be applied between the counter electrode and the MWCNT. The generated AC electric field interacts with induced charges on the MWCNT, which produces a periodic driving force. When the frequency of the input AC signal matched the mechanical resonance frequency of the MWCNT, obvious oscillation corresponding to the resonance mode of the cantilever MWCNT was observed (Fig. 18) and the resonance frequency of the MWCNT thereby determined. Using con-

Fig. 19 Bending and buckling of MWCNTs: (a) An original straight MWCNT, (b) The MWCNT is bent upwards all the way back onto itself, (c) The same MWCNT is bent all the way back onto itself in the other direction (Reprinted by permission from *Nature* [66]. Copyright 1997 Macmillan Publishers Ltd.)

tinuum beam mechanics, the bending modulus of the MWCNT was calculated from the measured resonance frequency and CNT geometry according to Eq. (2). The benefits of such an approach are the efficient method for driving mechanical resonances and, since the whole experiment is done inside a TEM, the ability to analyze the high aspect ratio nanostructures in detail.

3.2.2 Scanning force microscopy method

The atomic force microscope (AFM) operated in either lateral force mode, contact mode, or tapping mode has been the main tool in studying the mechanical response of individual CNTs under static load, and when in contact with surfaces. Falvo *et al* [66] used a nanomanipulator and contact mode AFM to manually manipulate and bend MWCNTs deposited on a substrate surface. The strong surface force between the MWCNTs and the substrate allowed such an operation to be performed. By intentionally creating large curvature bends in MWCNTs, buckles and periodic ripples were observed. These authors estimated that, based on the local curvature of the bend found, some MWCNTs could sustain up to 16% strain without obvious structural or mechanical failure (Fig. 19).

Wong *et al* [48] measured the bending modulus of individual MWCNTs using an AFM operated in lateral force mode (Fig. 20). The MWCNTs, deposited on a low friction MoS₂ surface, were pinned down at one end by overlaying SiO pads using lithography. AFM was then used to locate and measure the dimension of the MWCNT, and lateral force was applied at the different contact points along the length of the MWCNT (Fig. 20). By laterally pushing the MWCNT,

Fig. 20 Overview of one approach used to probe mechanical properties of nanorods and nanotubes: (a) SiC nanorods or carbon nanotubes were deposited on a cleaved MoS₂ substrate, and then pinned by deposition of a grid of square SiO pads. (b) Optical micrograph of a sample showing the SiO pads and the MoS₂ substrate. The scale bar is 8 μm . (c) An AFM image of a 35.3-nm-diameter SiC nanorod protruding from an SiO pad. The scale bar is 500 nm. (d) Schematic of beam bending with an AFM tip. The tip (triangle) moves in the direction of the arrow, and the lateral force is indicated by the red trace at the bottom. (e) Schematic of a pinned beam with a free end. The beam of length L is subjected to a point load P at $x=a$ and to a distributed friction force f (Reprinted with permission from [48]. Copyright 1997 American Association for the Advancement of Science.)

lateral force versus deflection data was recorded. The data was then analyzed using a beam mechanics model that accounted for the friction force and the concentrated lateral force as well as the rigidity of the beam. The bending modulus value for the MWCNT was obtained by fitting the measured force versus deflection curve. Such a method also allowed the bending strength to be determined by deflecting the beam past the critical buckling point.

Salvetat *et al* used another approach to deflect under load MWCNT [49] and SWCNT ropes [50] by depositing them onto a membrane having 200 nm pores (Fig. 21). By positioning the AFM tip directly on the midpoint of the CNT spanning the pore and applying an indentation force (Fig. 21) force versus deflection curves were obtained and compared with theoretical modeling based on beam mechanics. Elastic moduli for individual MWCNTs and separately for SWCNT bundles were deduced. In principle, such a measurement requires a well-controlled and stable environment to eliminate the errors induced by unexpected tip-surface interactions and instrument instability, as well as a very sharp AFM tip for the experiment.

The radial deformability of individual MWCNTs was studied by Shen *et al* [79] using an indentation method, and Yu *et al* [80] using a tapping mode method in AFM, respectively. Load was applied along the radial direction (perpendicular to the axial direction that is defined as along the long-axis of the CNT) of MWCNTs, and the applied force versus indentation depth curve was measured. Using the classic Hertz theory, the deformability of the MWCNT perpendicular to the long axis direction was obtained. The reader should please note that this is not the radial compress-

Fig. 21 (a) AFM image of a SWCNT bundle adhered to the polished alumina ultrafiltration membrane, with a portion bridging a pore of the membrane; (b) Schematic of the measurement: the AFM is used to apply a load to the nanobeam and to determine directly the resulting deflection. A closed-loop feedback ensured an accurate scanner positioning. Si₃N₄ cantilevers with force constants of 0.05 and 0.1 N/m were used as tips in the contact mode (from [50]).

ibility, because the force is not symmetrically applied in the radial direction (not isotropic). Thus one might think of this as *squashing* the MWCNT locally by indentation.

These two approaches are technically different. In the indentation method, the image scan is stopped and the AFM tip is held steady to apply a vertical force on a single point on the MWCNT through the extension and retraction of the piezoelectric tube along the z direction. A force versus indentation depth curve is obtained by monitoring the AFM cantilever deflection under the extension or retraction. In the tapping mode method, an off-resonance tapping technique is used so that the tapping force can be quantitatively controlled by adjusting the free cantilever amplitude and the set point. The set point is a control parameter in tapping mode AFM for keeping a constant cantilever amplitude (thus a constant distance between the AFM tip and the sample surface) in imaging scan mode. AFM images of each MWCNT are acquired using different set points, and force versus indentation depth curves are obtained by plotting the curve of the set point versus MWCNT height. The advantage of using the tapping mode method is that the *squashing* deformability of the MWCNT along its whole length can be obtained through several image acquisitions, though care must be taken to choose the appropriate tapping mode imaging parameters for such an experiment.

Walters *et al* [93] studied the elastic strain of SWCNT nanobundles by creating a suspended SWCNT bundle that was clamped at both ends by metal pads over a trench created with standard lithographic methods. Using an AFM operated in lateral force mode, they were able to repeatedly stretch and relax the nanoropes elastically as shown in (Fig. 22) including finally stretching to the breaking point to determine the maximum strain. The absolute force used to stretch the SWCNT bundle was not measured and the breaking strength was estimated by assuming the theoretical value of ~1 TPa for Young's modulus for the SWCNTs in the rope.

Fig. 22 Lateral force on SWCNT bundle as a function of AFM tip position. The four symbols represent data from four consecutive lateral force curves on the same rope, showing that this rope is straining elastically with no plastic deformation. Inset: The AFM tip moves along the trench, in the plane of the surface, and displaces the rope as shown (from [93]).

3.2.3 Measurement based on nanomanipulation

The response to axial tensile loading of individual MWCNTs was realized by Yu *et al* [29] using a new testing stage based on a nanomanipulation tool operating inside an SEM. The nanomanipulation stage allowed for the three-dimensional manipulation—picking, positioning, and clamping—of individual MWCNTs. The individual MWCNTs were attached to AFM probes having sharp tips by localized electron beam induced deposition (EBID) of carbonaceous material inside the SEM. A MWCNT so clamped between two AFM probes was then tensile loaded by displacement of the rigid AFM probe (Fig. 23), and the applied force was measured at the other end by the cantilever deflection of the other, compliant AFM probe. The measured force versus elongation data were converted, by SEM measurement of the MWCNT geometry, to a stress versus strain curve and the breaking strength of each MWCNT was obtained by measuring the maximum tensile loading force at break.

Yu *et al* [28] applied a similar approach for the tensile strength measurement of small bundles of SWCNTs. The entangled and web-like agglomeration of SWCNTs in raw samples made it difficult to find an individual SWCNT and resolve it by SEM or to pick out individual SWCNT nanobundles, so a modified approach was used for the experiment. SWCNT bundles having a strong attachment at one end to the sample surface were selected as candidates for the measurement. The free end of such a SWCNT bundle was then approached and attached to an AFM tip by the same EBID method outlined above. The AFM tip was used to stretch the SWCNT bundle to the breaking point and the same AFM tip also served as the force sensor to measure the applied force (Fig. 24). Stress versus strain curves for SWCNT bundles were obtained as well as the breaking

Fig. 23 (a) Individual MWCNT is clamped in place and stretched by two opposing AFM tips. (b) Schematic of the tensile loading experiment (Reprinted with permission from [29]. Copyright 2000 American Association for the Advancement of Science.)

strength; these stress versus strain curves were generated by assuming a model in which only the perimeter SWCNTs in a bundle actually carried the load. The reader is referred to [26] for the full explanation of this model.

The shear strength between the shells of a MWCNT is also an interesting subject for experimental study. Yu *et al* [11] were able to directly measure the friction force between the neighboring layers while pulling the inner shells out of the outer shells of an MWCNT using the same apparatus for measuring the tensile strength of individual MWCNTs. The possibility of such measurement was based on the discovery that tensile-loaded MWCNTs normally broke with a sword-in-sheath breaking mechanism [29]. The separated outer shell can still be in contact with the underlying inner shell in certain cases (in other cases, the *snap back* of the loading and force-sensing cantilevers leads to two separated fragments). The consecutive measurement of force and contact length (the overlap length between the outer shell and its neighbor) provided the necessary data for obtaining the dynamic and static shear strength between the shells.

A similar experiment done in a TEM rather than an SEM was that of Cumings *et al* [108] who used a TEM holder having a piezoelectric-driven translation stage for approaching and opening the end of a MWCNT. The MWCNT cap was opened by *eroding* it away using an electric discharge method inside the TEM [144]. The end of the exposed core part was then spot-welded to the moving probe using a short electrical pulse and the MWCNT was telescoped by drawing out the core part from the outer shell housing. It was then possible to disengage the core part from the welding spot, and observe the retraction of the core part back into its housing by the surface-driven forces (Fig. 25). By analyzing the surface force and the friction forces involved in such a retraction using published parameters and modeling, the upper limit values for the dynamic and static friction force between the shells were estimated, but not experimentally measured.

3.3 Challenges and new directions

The new developments in the area of nanoscale manipulation and measurement as reflected in the studies presented in the last section have certainly helped our understanding of the mechanics of CNTs. Since CNTs possess unique one-

Fig. 24 Schematic showing the principle of the experiment for the measurement of the tensile strength of SWCNT bundles. The gray cantilever indicates where the cantilever would be if no rope were attached on the AFM tip after its displacement upward to achieve tensile loading.

dimensional structures that maintain their conformation while being manipulated (in contrast, eg, to biomolecules or certain polymer systems), they represent a *nano-tinker toy* for manipulation on the nanoscale. Therefore, such types of approaches also provide a window on current capabilities for exploring and exploiting the nano-world, and provide an avenue for future advancement in methods and tools useful in nanotechnology. To be kept in mind is that mechanical characterization takes in general a totally different approach than does electrical characterization. Mechanical characterization normally requires dynamic physical interaction with the object, for example, in the case for CNT, stretching, bending, compressing and twisting with nanometer positioning accuracy, while performing measurement with nano-Newton force resolution and nanometer dimensional change resolution. Thus, in order for a successful and reliable mechanical study on nanoscale structures to be made, extreme care must be taken to evaluate the three-dimensional stability and accuracy of the instrument, and the effect of any significant external factors such as surface contact, mechanical attach-

ment, stray electric charge, and so on. The experiments described in the last section represent the current state of the art in the manipulation and mechanical characterization of CNTs and should provide useful references for further instrument development, which can then be applied to many other low dimensional nano-structures for mechanical studies.

But what has the community not yet achieved? We have not yet measured the tensile loading response of an individual SWCNT, nor have we applied a known torque and controllably introduced a twist or series of twists along a CNT. The challenges here include: first, the visualization, manipulation, precise placement, and fixation of a *flexible* one-dimensional nanostructure, the SWCNT, onto a device having displacement and force sensing capabilities for the tensile measurement; second, a technical breakthrough in generating repeatable coaxial rotation with sub-nanometer runoff and with sufficient force output for applying torque to CNT. The influence of environment on NT mechanics—such as effects of temperature, chemical environment, or loading rate—has not yet been explored in any detail; nor do we have a clear and detailed picture of the initial defect distribution, or the nucleation, propagation, and ultimate failure resulting from defects. From the experimental perspective, such advances will come with new approaches and automated tools with sub-nanometer or atomic scale resolving power and stability generated by innovative thinking. It is clear that to attain further advances in nanoscale mechanics, focused effort is necessary in developing new measurement tools that can be integrated into high spatial resolution imaging instruments and that incorporate micro- or nano-electromechanical system designs.

4 SIMULATION METHODS

There are two major categories of molecular simulation methods for NT systems: classical molecular dynamics (MD) and *ab initio* methods. In general, *ab initio* methods give more accurate results than MD, but they are also much more computationally intensive. A hybrid method, tight-binding molecular dynamics (TBMD), is a blend of certain features from both MD and *ab initio* methods. In addition to these methods, continuum and multiscale approaches have also been proposed.

4.1 *Ab initio* and tight-binding methods

The central theme of *ab initio* methods is to obtain accurate solutions to the Schrödinger equation. A comprehensive description of these methods can be found in the book by Ohno *et al* [145]. Some notation is also adapted in this section. For general background in quantum mechanics, the reader is referred to any of the standard textbooks, such as [146–150]. In general, the state of a particle is defined by a wave function ψ based on the well-known wave-particle duality. The Schrödinger equation is

$$H\psi = E\psi \quad (18)$$

where H is the Hamiltonian operator of the quantum mechanical system, and ψ is the energy eigenfunction corresponding to the energy eigenvalue E .

Although the phrase *ab initio* is used, analytical or exact solutions are available only for a very limited class of problems. In general, assumptions and approximations need to be made. One of the most commonly used approximations is the Born-Oppenheimer approximation. In this approximation, it is assumed that the electrons are always in a steady state derived from their averaged motion since their positions change rapidly compared to the nuclear motion. Therefore, the motion of the electrons can be considered separately from the motion of the nuclei—as if the nuclei were stationary.

For an N-electron system, the Hamiltonian operator for each electron can be expressed as

$$H_i = -\frac{1}{2}\nabla_i^2 + \sum_{j>i}^N \frac{1}{|r_i - r_j|} + v(r_i) \quad (19)$$

The Hamiltonian operator in the above equation is composed of three parts. The first term in Eq. (19) gives the kinetic energy when operating on the electron wavefunction, the second term gives the electron-electron Coulomb interaction, and the last term comes from the Coulomb potential from the nuclei. The total Hamiltonian operator of the N-electron system is then

$$H = \sum_{i=1}^N H_i \quad (20)$$

and the electron state is solved from the following eigenvalue equation

$$H\psi_{\lambda_1, \lambda_2, \dots, \lambda_N} = E_{\lambda_1, \lambda_2, \dots, \lambda_N} \psi_{\lambda_1, \lambda_2, \dots, \lambda_N} \quad (21a)$$

in which λ_i denotes an eigenstate that corresponds to the one-electron eigenvalue equation:

$$H_i \psi_{\lambda_i} = E_{\lambda_i} \psi_{\lambda_i} \quad (21b)$$

Because obtaining exact solutions to Eq. (21b) is generally very difficult, approximation methods have been developed. In the following, we will introduce two of the most commonly used approaches.

4.1.1 Hartree-Fock approximation

In the Hartree-Fock approximation [151–153], the ground state of the Hamiltonian H is obtained by applying the variational principle with a normalized set of wave functions ψ_i . The methodology is identical to the Ritz method, ie, to seek the solution by minimizing the expectation value of H with a trial function:

$$\langle \psi | H | \psi \rangle = \sum_{s_1} \sum_{s_2} \sum_{s_3} \int \psi^* H \psi dr_1 dr_2 \cdots dr_N \quad (22)$$

One possible choice of the trial function is the Slater determinant of the single-particle wavefunctions, ie,

$$\psi = \frac{1}{\sqrt{N!}} \begin{vmatrix} \psi_1(1) & \psi_2(1) & \dots & \psi_N(1) \\ \psi_1(2) & \psi_2(2) & & \psi_N(2) \\ \cdot & \cdot & & \cdot \\ \psi_1(N) & \psi_2(N) & & \psi_N(N) \end{vmatrix} \quad (23)$$

In the above equation, the number in the bracket indicates the particle coordinate, which is composed of the spatial coordinate r and internal spin degree of freedom. The subscript denotes the energy level of the wave function and $\psi_{\lambda}(i)$ forms an orthonormal set.

The Hamiltonian, on the other hand, is decomposed into a one-electron contribution H_0 and two-body electron-electron Coulomb interaction U as follows:

$$H = \sum_i H_0(i) + \frac{1}{2} \sum_{i,j} U(i,j) \quad (24)$$

The one-electron contribution H_0 consists of the kinetic energy and nuclear Coulomb potential

$$H_0(i) = -\frac{1}{2}\nabla_i^2 + v(r_i) \quad (25)$$

in which

$$v(r_i) = -\sum_j \frac{Z_j}{|r_i - R_j|} \quad (26)$$

with Z_j being the nuclear charge of the j th atom. The two-body electron-electron interaction is given as the Coulomb interaction

$$U(i,j) = \frac{1}{|r_i - r_j|} \quad (27)$$

With the trial function and decomposition of H , the expectation value of the Hamiltonian can then be rewritten as

$$\begin{aligned} \langle \psi | H | \psi \rangle &= \sum_{\lambda=1}^N \langle \psi_{\lambda} | H_0 | \psi_{\lambda} \rangle + \frac{1}{2} \sum_{\lambda, \nu} \langle \psi_{\lambda} \psi_{\nu} | U | \psi_{\lambda} \psi_{\nu} \rangle \\ &\quad - \frac{1}{2} \sum_{\lambda, \nu} \langle \psi_{\lambda} \psi_{\nu} | U | \psi_{\nu} \psi_{\lambda} \rangle \end{aligned} \quad (28)$$

Applying the variational principle to Eq. (28), it can be shown that solving the electron state of the system can now be approximated by solving the following equation for the one-electron wavefunction:

$$\begin{aligned} H_0 \psi_{\lambda}(i) + \left[\sum_{\nu=1}^N \sum_{s_j} \int \psi_{\nu}^*(j) U(i,j) \psi_{\nu}(j) dr_j \right] \psi_{\lambda}(i) \\ - \left[\sum_{\nu=1}^N \sum_{s_j} \int \psi_{\nu}^*(j) U(i,j) \psi_{\lambda}(j) dr_j \right] \psi_{\nu}(i) = \varepsilon_{\lambda} \psi_{\lambda}(i) \end{aligned} \quad (29)$$

in which ε_j is the Lagrangian multiplier used to enforce the orthonormal condition for the eigenfunction. The Hartree-Fock approximation has been used in many *ab initio* simulations. A more detailed description and survey of this method can be found in [154].

4.1.2 Density functional theory

The density functional theory was originally proposed in a paper by Hohenberg and Kohn [155]. In this paper, they showed that the ground-state electronic energy is a unique functional of the electronic density. In most cases, the potential due to the external field comes mainly from the nuclei. The electronic energy can then be expressed as

$$E = T[\rho(r)] + \int \frac{[\rho(r)\rho(r')]}{|r-r'|} drdr' + \int V_N(r) dr + E_{XC}[\rho(r)] \quad (30)$$

In Eq. (30), $T[\rho(r)]$ is the kinetic energy and is a function of the electron density, the second term represents the electrostatic potential, the third term denotes the contribution from the nuclei, and the last term is the exchange-correlation functional. Kohn and Sham [156] presented a procedure to calculate the electronic state corresponding to the ground state using this theory, and their method is generally referred to as the *local-density approximation* or LDA. LDA is another type of widely used *ab initio* method. The term *local-density* comes from the assumption that the exchange-correlation function corresponding to the homogeneous electron gas is used. This assumption is only valid locally when the inhomogeneity due to the presence of the nuclei is small.

The essence of the LDA method is to obtain the ground state by introducing the variational principle to the density functional. This leads to a one-electron Schrödinger equation (also called the Kohn-Sham equation) for the Kohn-Sham wavefunction ψ_λ

$$\left\{ -\frac{1}{2}\nabla^2 + v(\mathbf{r}) + \int \frac{\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} d\mathbf{r}' + \mu_{XC}[\rho](\mathbf{r}) \right\} \psi_\lambda(\mathbf{r}) = \varepsilon_\lambda \psi_\lambda(\mathbf{r}) \quad (31)$$

Note that the term $\mu_{XC}[\rho](r)$ is the derivative of the exchange-correlation functional with respect to the electron density. Different functional forms for the exchange-correlation energy have been proposed [157–160]. The problem is reduced to obtaining the solutions to systems of one-electron equations. Once ψ_λ and ε_λ are solved, the total energy can be obtained from (30). The major advantage of using LDA is that the error in the electron energy is second-order between any given electron density and ground state density.

The solution procedure requires an iterative diagonalization process, which in general involves $O(N^3)$ order of computation. A single electron wavefunction with a plane wave basis and pseudopotential have been used in the application of the LDA method [161]. Major improvements have been made using the Car-Parrinello MD method [162] and conjugate gradient (CG) method [161]. The Car-Parrinello method reduces the order from $O(N^3)$ to $O(N^2)$. As shown in [161], the CG method can even be more efficient.

4.1.3 Tight-binding method

The tight-binding theory was originated by Slater and Koster [163]. The advantage of the tight-binding method is that it can handle a much larger system than the *ab initio* method

while maintaining better accuracy than MD simulation. A survey of the method can be found in [164]. In the tight-binding method, a linear combination of atomic orbitals (referred to as LCAO) is adopted in the wave function. Although the exact forms of the basis are not known, the Hamiltonian matrix can be parameterized, and the total energy and electronic eigenvalues can be deduced from the Hamiltonian matrix. The interatomic forces are evaluated in a straightforward way based on the Hellmann-Feynman theorem and the rest of the procedure is almost identical to the MD simulation. For this reason, sometimes the tight-binding method is also referred to as the tight-binding MD method or simply TBMD.

As shown by Foulkes and Haydock [165], the total energy can be expressed as the sum of the eigenvalues of a set of occupied non-self-consistent one-electron molecular eigenfunctions in addition to certain analytical functions. The analytical function is usually assumed to take the form of a pair-additive sum. For example, the total energy can be given as

$$E = \sum_i \sum_{j>i} E_{ij} + \sum_k \varepsilon_k \quad (32)$$

The first term on the right side is the inter-atomic interaction and the second term is the sum of the energies of occupied orbitals. A simple scheme in constructing the second term is to expand the wave function in a localized orthonormal minimal basis with parameterized two-center Hamiltonian matrix elements. The parameterization process can be performed by fitting to results from the *ab initio* methods [166,167], or computing the matrix exactly based on the localized basis [168–170]. A major problem with the TBMD method is the way that the parameterization of the Hamiltonian limits its applicability, or *transferability* as referred to in the computational physics community. As a simple example, when one switches from diamond structure to graphite, the nature of the nearest neighbor changes. In the early development of TBMD, Harrison [164] attempted to use a set of universal parameters; this approach turns out to be neither transferable nor accurate. The solution is then to add in modifications [171,172], or to use a completely different basis [173].

4.2 Classical molecular dynamics

Many reviews are available on the subject of classical molecular dynamics [174–176]. MD is essentially a particle method [177,178] since the objective is to solve the governing equations of particle dynamics based on Newton's second law, ie,

$$m_i \frac{d^2 \mathbf{r}_i}{dt^2} = -\nabla V \quad (33)$$

in which m_i and \mathbf{r}_i are the mass and spatial coordinates of the i th atom, respectively, V is the empirical potential for the system, and ∇ denotes the spatial gradient. Due to the small time scale involved, explicit integration algorithms such as the Verlet method [179,180] and other high-order methods are commonly used to ensure high order accuracy.

An alternate but equivalent approach is to solve the Hamiltonian system of ordinary differential equations

$$dp_i/dt = -\partial H/\partial q_i \quad (34)$$

$$dq_i/dt = \partial H/\partial p_i \quad (35)$$

in which (q_i, p_i) are the set of canonically conjugate coordinates and momenta, respectively. H is the Hamiltonian function given as

$$H = \sum_{i=1}^N \frac{p_i^2}{2m_i} + V \quad (36)$$

Symplectic integrators [181] have been developed to solve the above Hamiltonian equations of motion. The major advantages of this class of methods are that certain invariant properties of the Hamiltonian system can be preserved [181] and it is easy to implement in large-scale computations.

4.2.1 Bonding potentials

The basic formulation of MD requires that the spatial gradient of the potential function V be evaluated. Different empirical potentials for an NT system have been developed to satisfy this requirement. Allinger and co-workers developed [182,183] a molecular mechanics force field #2 (MM2) and an improved version known as the MM3 force field. Their model has been applied in the analysis of a variety of organic and inorganic systems. It should be noted that MM2/MM3 is designed for a broad class of problems. It is expected that the model may not work well under certain conditions. For example, the model is known to yield unrealistic results when inter-atomic distance is in the region of highly repulsive interactions. Mayo *et al* [184] presented a generic force field based on simple hybridization considerations. The proposed form of the potential is a combination of bond length (two-body), angle bend (three-body) and torsion (four-body) terms. This empirical model has been used by Guo *et al* [185] in the analysis of crystal structures of C_{60} and C_{70} , and by Tuzun *et al* [186,187] in the analysis of carbon NT filled with fluid and inert gas atoms. Like the MM2/MM3 model, this force field covers a wide range of nonmetallic main-group elements.

Another class of empirical potentials for CNT is characterized by the quantum-mechanical concept of bond order formalism originally introduced by Abell [188]. An alternate interpretation of this formalism can also be found in [189]. Using a Morse-type potential, Abell showed that the degree of bonding universality can be well maintained in molecular modeling for similar elements. Tersoff [133–136] introduced this important concept for the modeling of Group IV elements such as C, Si, and Ge, and reasonably accurate results were reported. In Tersoff-Abell bond order formalism, the energy of the system is a sum of the energy on each bond. The energy of each bond is composed of a repulsive part and attractive part. A bond order function is embedded in the formulation. The bond order depends on the local atomic environment such as angular dependency due to the bond angles. Nordlund *et al* [190] modified the Tersoff potential such that the interlayer interaction is also considered. Bren-

ner [35] made further improvements to the Tersoff potential by introducing additional terms into the bond order function. The main purpose of these extra terms is to correct the overbinding of radicals. Compared with the Tersoff potential, Brenner's potential shows robustness in the treatment of conjugacy, and it allows for forming and breaking of the bond with the correct representation of bond order. Brenner's potential has enjoyed success in the analysis of formation of fullerenes and their properties [34,191–193], surface patterning [194], indentation and friction at nanoscale [195–204], and energetics of nanotubes [34]. An improved version of Brenner's potential has recently been proposed [189,205]. Based on the approximation of the many-atom expansion for the bond order within the two-center, orthogonal tight-binding (TB) model, Pettifor and Oleinik [206,207] have derived analytical forms that handle structural differentiation and radical formation. The model can be thought of as semi-empirical since it is partly derived from TB. Application of this model to hydrocarbon systems can be found in [206]. Depending on the range of applicability, a careful selection of potential model for a specific problem is needed.

4.2.2 Interlayer potentials

Another important aspect of modeling in the analysis of CNT systems is the interlayer interaction. There are two major functional forms used in the empirical model: the inverse power model and the Morse function model. A very widely used inverse power model, the Lennard-Jones (LJ) potential, was introduced by Lennard-Jones [208,209] for atomic interactions

$$u(R_{ij}) = 4\epsilon \left[\left(\frac{R}{R_{ij}} \right)^{12} - \left(\frac{R}{R_{ij}} \right)^6 \right] \quad (37)$$

where R_{ij} denotes the inter-atomic distance between atoms i and j , σ is the collision diameter (the inter-atomic distance at which $u(R)$ is zero), and ϵ is the energy at the minimum in $u(R_{ij})$. This relationship is shown in Fig. 26. In the figure, the energy u , interatomic distance R and interatomic force F are all normalized as $u^* = u/\epsilon$, $r^* = R_{ij}/R$, and F^*

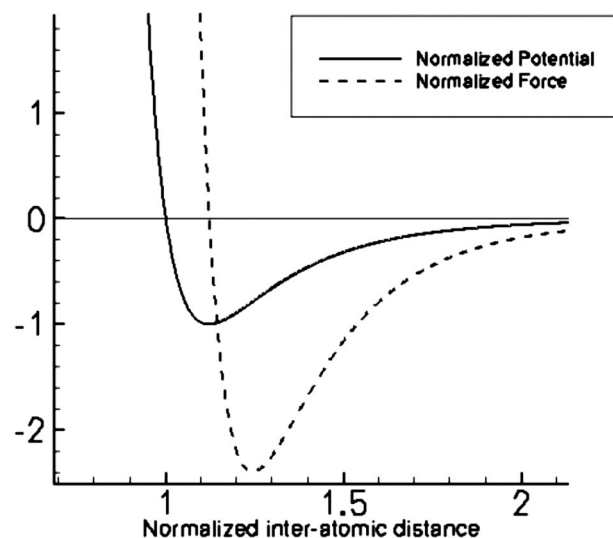

Fig. 26 The pair potential and inter-atomic force in a two-atom system

Table 1. Model parameters for LJ potential

Parameter source	A	σ	y_0
LJ1 [209]	$24.3 \times 10^{-79} \text{ J.m}^6$	1.42 Å	2.7
LJ2 [210]	$32 \times 10^{-79} \text{ J.m}^6$	1.42 Å	2.742

$=FR/\varepsilon$. The corresponding force between the two atoms as a function of inter-atomic distance is also shown in Fig. 26, and can be expressed as

$$F_{ij} = -\frac{\partial u(R_{ij})}{\partial R_{ij}} = 24 \frac{\varepsilon}{R} \left[2 \left(\frac{R}{R_{ij}} \right)^{13} - \left(\frac{R}{R_{ij}} \right)^7 \right] \quad (38)$$

For the carbon-carbon system, the LJ potential energy has been treated by Girifalco and Lad [210,211] and is given as

$$\phi_i = \frac{A}{\sigma^6} \left[\frac{1}{2} y_0^6 \frac{1}{\left(\frac{r_i}{\sigma} \right)^{12}} - \frac{1}{\left(\frac{r_i}{\sigma} \right)^6} \right] \quad (39)$$

In Eq. (39), σ is the bond length, y_0 is a dimensionless constant, and r_i is the distance between the i th atom pair. Two sets of parameters have been used: one for a graphite system [210] and the second for a fcc crystal composed of C_{60} molecules [211]. The converted parameters from the original data are given in Table 1.

Wang *et al* [212] derived the following Morse-type potential for carbon systems based on local density approximations (LDA):

$$U(r) = D_e \left[(1 - e^{-\beta(r-r_e)})^2 - 1 \right] + E_r e^{-\beta' r} \quad (40)$$

where $D_e = 6.50 \times 10^{-3}$ eV is the equilibrium binding energy, $E_r = 6.94 \times 10^{-3}$ eV is the hard-core repulsion energy, $r_e = 4.05$ Å is the equilibrium distance between two carbon atoms, $\beta = 1.00/\text{Å}$ and $\beta' = 4.00/\text{Å}$. In a comparison study by Qian *et al* [213], it was found that the two LJ potentials yield much higher atomic forces in the repulsive region than the LDA potential, while in the attractive region, the LDA potential gives a much lower value of the binding energy than the two LJ potentials.

Fig. 27 Comparison of EOS for graphite using different models with experimental data (Reprinted from [213] with permission from Elsevier Science.)

Further verification of this LDA potential is obtained by computing the equation of state (EOS) for a graphite system by assuming no relaxation within the graphene plane. The results are compared with published experimental data by Zhao and Spain [214] (referred to as EXP1) and by Hanfland *et al* (referred to EXP2) [215], and with the *ab initio* treatment (which included in-plane relaxation and treated an infinite crystal) by Boettger [216]. The LDA model fits this experimental data, and Boettger's model, reasonably well. The LJ potential, in contrast, deviates strongly from the experimental high-pressure data for graphite (and Boettger's high level computational treatment) where the relative volume is, of course, smaller (Fig. 27). Based on this comparison, Qian *et al* [213] proposed to use LDA for inter-atomic distances less than 3.3 Å and LJ for inter-atomic distance greater than 3.4 Å. The transition region is handled by curve fitting to ensure the continuity. A comparison of this model with the rest is also shown in Fig. 27. Girifalco *et al* [217] replaced the discrete sum of the atom pair potentials with a continuous surface integral. In their approach, different model parameters were derived for the cases of two parallel nanotubes and between C_{60} and nanotubes, although the LJ functional form is unchanged.

One of the major disadvantages of the potentials mentioned above is that the difference in interlayer binding energy of the AA and the AB stacking configurations for two rigid graphitic layers spaced at ~ 0.34 nm is probably not well represented; in short, the *corrugation* in the interlayer energy, due to the *pi* bonds projecting orthogonal to the plane of the layers, is not well captured. In addition, this registration effect also leads to unique nanoscale tribological features. Particularly, the corrugation between neighboring layers will play a central role in the friction present in such a nano-bearing system. The effects of interlayer registration between CNT and the surface it is sliding on have been studied recently in a number of interesting experiments by Falvo *et al* [218–221]. In these experiments, atomic force microscopy (AFM) is used to manipulate the MWCNTs on the surface of graphite. A transition of slip-to-roll motion was reported as the MWCNT was moved to certain particular positions. This phenomenon uncovers the effects of commensurancance at the nanoscale. Both MD [222] and quasi-static simulation [223] have been performed to verify the experiments. Kolmogorov and Crespi [224] developed a new *registry-dependent graphitic potential* which accounts for the exponential atomic-core repulsion and the interlayer delocalization of π orbitals in addition to the normal two-body van der Waals attraction. This model derives an approximately 12 meV/atom difference between the AB stacking and the AA stacking. As discussed in Section 2.2.3, Yu *et al* [83] applied this model to treat the mechanics of a free standing twisted MWCNT observed experimentally. In more general settings than, eg, perfectly nested perfect cylinders or two perfectly parallel graphene sheets, the formulation of appropriate models of interlayer interactions remains an important challenge for modeling. Indeed at the nanoscale, the importance of surface interactions cannot be underestimated, and we envision

further work by theoreticians and experimentalists to treat problems where some useful discussion between the two camps can be achieved.

4.3 Continuum and multiscale models

Despite constant increases in available computational power and improvement in numerical algorithms, even classical molecular dynamics computations are still limited to simulating on the order of 10^6 – 10^8 atoms for a few nanoseconds. The simulation of larger systems or longer times must currently be left to continuum methods. From the crystal elasticity approach in Section 2.4, one might immediately see the possibility of applying the finite element method (FEM) to the computational mechanics of nanotubes since the continuum concept of stress can be extracted from a molecular model. However, the fundamental assumption of the continuum approximation, that quantities vary slowly over lengths on the order of the atomic scales, breaks down in many of the most interesting cases of nanomechanics. Thus it would be very useful to have in hand a method that allows the use of a molecular dynamics-like method in localized regions, where quantities vary quickly on the atomic length scale, seamlessly blended with a continuum description of the surrounding material in which, presumably, small scale variations are unimportant or can be treated in an averaged sense.

Several promising methods have been developed toward this goal. The quasicontinuum method, introduced by Tadmor *et al* [125,126] and extended and applied to several different problems over the last few years [225–233], gives a theory for bridging the atomistic and continuum scales in quasistatic problems. In this method, a set of atoms L making up a Bravais lattice has selected from it a subset L_h . A triangulation of this subset allows the introduction of finite element-like shape functions $\varphi_h(\mathbf{l}_h)$ at lattice points $\mathbf{l}_h \in L_h$, allowing the interpolation of quantities at intermediate points in the lattice. For example, the deformed coordinates \mathbf{q} at a lattice point \mathbf{l} can be interpolated:

$$\mathbf{q}_h(\mathbf{l}) = \sum_{\mathbf{l}_h \in L_h} \varphi_h(\mathbf{l}) \mathbf{q}_h(\mathbf{l}_h) \quad (41)$$

In this way, the problem of the minimization of energy to find equilibrium configurations can be written in terms of a reduced set of variables. The equilibrium equations then take the form, at each reduced lattice point \mathbf{l}_h :

$$\mathbf{f}_h(\mathbf{l}_h) = \sum_{\mathbf{l} \in L} \mathbf{f}(\mathbf{l}) \varphi_h(\mathbf{l}) = \mathbf{0} \quad (42)$$

The method is made practical by approximating summations over all atoms, as implied by the above equation, by using summation rules analogous to numerical quadrature. These rules rely on the smoothness of the quantities over the size of the triangulation to ensure accuracy. The final piece of the method is therefore the prescription of adaptivity rules, allowing the reselection of representative lattice points in order to tailor the computational mesh to the structure of the deformation field. The criteria for adaptivity are designed to

allow full atomic resolution in regions of large local strain, for example very close to a dislocation in the lattice.

The quasicontinuum method has been applied to the simulation of dislocations [125,126,230,233], grain boundary interactions [225,228], nanoindentation [126,228,229], and fracture [226,227]. An extension of the method to finite temperatures has been proposed by Shenoy *et al* [234]. We have successfully extended the quasi-continuum method to the analysis of the nanotube (CNT) system, although careful treatment is needed. The major challenge in the simulation of CNTs using the quasicontinuum method is the fact that CNT is composed of atomic layers. The thickness of each layer is the size of one carbon atom. In this case, it can be shown that the direct application of the Cauchy-Born rule results in inconsistency in the mapping. Arroyo and Belytskhko [235] corrected this inconsistent mapping by introducing the concept of exponential mapping from differential geometry. An alternate approach is to start with the variational principle and develop a method without the Cauchy-Born rule. We have developed the framework of this method with the introduction of a meshfree approximation [236–242]. For a survey of meshfree and particle methods and their applications, please see [178]; an online version of this paper can be found at <http://www.tam.nwu.edu/wkl/liu.html>. In addition, two special journal issues [243,244] have been devoted to this topic. Odegard *et al* [245] have proposed modeling a CNT as a continuum by equating the potential energy with that of the representative volume element (RVE). This assumption seems to be the same as that in the quasicontinuum method; however, the Born Rule is not used. The method has been recently applied in the constitutive modeling of CNT reinforced polymer composite systems [246].

The meshfree method has been directly applied by Qian *et al* [213] in the modeling of a CNT interacting with C_{60} . The C_{60} molecule is, on the other hand, modeled with a molecular potential. The interaction between the C_{60} and the continuum is treated based on the conservation of momentum. The interaction forces on the CNT are obtained through the consistent treatment of the weak formulation.

In this approach, a continuous deformation mapping will be constructed through the meshfree mapping function ϕ . The final form of the discrete equation can be shown to be:

$$f_I^{\text{ext}} + f_I^{\text{int}} + f_I^{\text{inert}} = 0 \quad (43)$$

The internal force term that is related to the internal energy is expressed as:

$$f_I^{\text{int}} = \sum_{\mathbf{l} \in I} w_{\mathbf{l}} f_{\mathbf{l}}(\varphi(r, \theta)) \quad (44)$$

Another approach to the coupling of length scales is the FE/MD/TB model of Abraham *et al* [247,248]. In this method, three simulations are run simultaneously using finite element (FE), molecular dynamics (MD) and semi-empirical tight-binding (TB). Each simulation is performed on a different region of the domain, with a coupling imposed in *handshake* regions where the different simulations overlap. The method is designed for implementation on supercomputers via parallel algorithms, allowing the solution of large problems. One

example of such a problem is the propagation of a crack in a brittle material [247]. Here, the TB method is used to simulate bond breaking at the crack tip, MD is used near the crack surface, and the surrounding medium is treated with FE. This method has also been used by Nakano *et al* in large-scale simulations of fracture [249]. Rafii-Tabar *et al* [250,251] have presented a related method combining FE and MD for the simulation of crack propagation.

A related method, coarse-grained molecular dynamics (CGMD) [252,253], has been introduced as a replacement for finite elements in the FE/MD/TB simulations. In this approach, the continuum-level (or coarse-grained) energy is given by an ensemble average over the atomic motions in which the atomic positions are constrained to give the proper coarse-scale field. In this way, the fine scale quantities that are not included in the coarse scale motion are not neglected completely, as their thermodynamic average effect is retained.

We are currently developing a method for the coupling of continuum and MD simulations at finite temperature which, rather than enforcing coupling through boundary conditions in a handshake region, allows the continuum and MD representations to coexist in areas of interest in the computational domain. The methodology of the multiscale method can be traced back to the original paper by Liu *et al* [254,255], and has been successfully applied in the multiple-scale problems involving strain localization [256] boundary layers [257] and coupling of finite elements with meshfree shape functions [258]. In the current problem setting, this is done by writing a multiple-scale decomposition of the atomic displacements u_α in terms of finite element node displacements d_I and MD displacements d_α ; the total scale is given by the usual finite element interpolation, plus the MD displacements, minus the projection of the MD displacements onto the finite element basis. Designating this projection operator as P :

$$u_\alpha = \sum_I N_I(x_\alpha) d_I + d_\alpha - P d_\alpha \tag{45}$$

where $N_I(x_\alpha)$ is the finite element shape function for node I evaluated at atom α . The key to the method is the subtraction of the projection of d_α , which we term the *bridging scale*

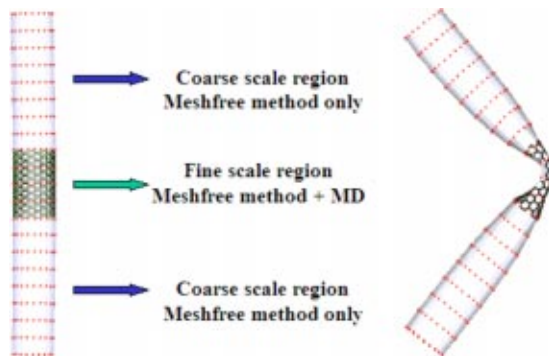

Fig. 28 Multiscale analysis of carbon nanotube

and which allows for a unique decomposition into coarse and fine scales. With this decomposition, the Lagrangian (kinetic minus potential energies) can be written:

$$L(d_I, \dot{d}_I, d_\alpha, \dot{d}_\alpha) = \sum_{I,J} \frac{1}{2} \dot{d}_I M_{IJ} \dot{d}_J + \sum_{\alpha,\beta} \frac{1}{2} \dot{d}_\alpha M_{\alpha\beta} \dot{d}_\beta - U(d_I, d_\alpha) \tag{46}$$

where M_{IJ} is the usual finite element mass matrix, $M_{\alpha\beta}$ is a fine-scale mass matrix, and U is the potential energy function. The equations of motion that can be derived from this Lagrangian are the usual finite element equation (plus a contribution to the internal force due to d_α), and the standard MD equations of motion (plus a driving term due to the continuum scale), ie,

$$\sum_J M_{IJ} \ddot{d}_J = - \frac{\partial U(d_I, d_\alpha)}{\partial d_I} \tag{47a}$$

$$\sum_\beta M_{\alpha\beta} \ddot{d}_\beta = - \frac{\partial U(d_I, d_\alpha)}{\partial d_\alpha} \tag{47b}$$

These equations can be solved using existing FE and MD codes along with suitable methods for exchanging information about internal forces and boundary conditions. An energy equation can also be derived by considering the continuum level temperature to be described by the fluctuations in the fine scale motions. Shown in Fig. 28 is an example of implementing the multiscale method. It can be seen that the meshfree discretization and MD coexist and are coupled in the fine scale region. For the coarse scale region, a meshfree approximation is used. For the case shown in Fig. 28, the error in the bending energy is less than 1% when compared with a purely MD approach. A systematic description of this method is to be described in [259].

5 MECHANICAL APPLICATIONS OF NANOTUBES

5.1 Nanoropes

As discussed in Section 2.3.2, the primary product of current methods of SWCNT synthesis contains not individual, sepa-

Fig. 29 3D section of a wire and force components in the x-z and y-z planes

rated SWCNTs, but rather bundles of closest-packed SWCNTs [86,91]. Load transfer to the individual SWCNTs in these bundles is of paramount importance for applications involving tensile load-bearing. It is estimated that to achieve load transfer so that the full bundle cross-section would be participating in load-bearing up to the intrinsic SWCNT breaking strength, the SWCNT contact length must be on the order of 10–120 microns. There is strong evidence, however, that the typical length of individual SWCNTs in such bundles is only about 300 nm [112,113].

From continuum mechanics analysis of other types of wire or fiber forms [260,261], it is found that twisting the wires or *weaving* the fibers can lead to a cable or rope that has much better load transfer mechanism in tension than a straight bundle would have. Compared with parallel wires, the major difference in terms of the mechanics of a wire rope is that wire ropes have a radial force (in the direction of vector \mathbf{N} and \mathbf{N}' as shown in Fig. 29) that presses the surrounding wires to the core.

Correspondingly, the advantages of having wires in the form of a rope are:

- A rope provides better load transfer and structural reliability. For example, when one wire component breaks, the broken sections of that particular wire can still bear load transferred from the other wires through the strong friction force that is a consequence of the radial compression.
- Wire rope has a smaller bending stiffness, therefore it is desirable for applications in which the rope has to be bent frequently. The fatigue life is significantly longer.
- The radial force component gives the rope structure more stability than wires in parallel.

Based on preliminary modeling we have done of a 7-element twisted SWCNT bundle, it is believed that better load transfer in tension can be achieved by making nanoscale ropes

and textiles of SWCNTs. We briefly describe some of these new mechanisms and issues below; a detailed analysis is given in [262]. We have used MD based on the empirical Tersoff-Brenner potential to analyze a bundle of SWCNTs under twist. A single strand composed of six (10,10) SWCNTs with length of 612 Å surrounding a core (10,10) tube is studied. Both ends of the core tube are fixed and a twist around the center of the core on the six neighboring SWCNTs is applied at an angular velocity of $20\pi/\text{ns}$ (see Fig. 30 for the cross-section before (a) and after (b) relaxation). The geometric parameters corresponding to the initial configuration are: $r=6.78$ Å, $d=3.44$ Å, $R=2r+d=17$ Å, $\theta=\pi/3$.

Shown in Fig. 31 are three snapshots of the deformation of the bundle after twisting is introduced. The corresponding change in the cross-section is shown in Fig. 32 at the mid-point of the bundle. Clearly, radial deformation strongly depends on the twist angle. Further calculation [263] is performed on a bundle of SWCNT with the same cross-sectional configuration but with a length of 153.72 Å. The total number of atoms is 17500. Both ends of the core tube

Fig. 30 (a) geometric parameters used in relaxed nanotube bundles; (b) configuration of bundled nanotubes after relaxation

Fig. 31 Snapshots of twisting of the SWCNT bundle

Fig. 32 Change in cross-section at the mid-point of the SWNT bundle as a function of twist angle (From a–f, the twisting angles are 30, 60, 90, 120, 150, and 180 degrees, respectively.)

Fig. 33 Transferred load as a function of twisting angle

are fixed and a twist around the center of the core on the 6 neighboring SWCNTs is applied to achieve a desired angle of twist. After this the whole twisted structure is relaxed to obtain the equilibrium configuration. A constant incremental displacement is then imposed on the core tube while holding the surrounding nanotubes fixed. Plotted in Fig. 33 are the axial loads transferred to the inner tube as a function of the twist angle. We use this transferred axial load as an index for the effectiveness of the load transfer mechanism. As can be seen in Fig. 33, small twist has very little effect. For the case of 0 degrees (no twist), a force of only ~ 0.048 eV/Å is transferred to the center tube, an indication of a very smooth inner-tube contact condition. However, for a twist angle of 120 degrees, the transferred load increases to 1.63 eV/Å, about 34 times higher. Our calculation also indicates that too much twist results in unstable structures, ie, the inner tube is being *squeezed out* when the twisting angle is 180 degrees or higher. This calculation clearly indicates a great enhancement in the load transfer mechanism can be achieved by making the nano-rope. More study on quantitatively determining the effects of various factors can be found in [262,263]. For these significantly collapsed SWCNTs in highly twisted SWCNT bundles, the effective contact area is significantly increased, and this may contribute to better load transfer. In such twisted SWCNT bundles, the load transfer is likely enhanced by an expected increase in shear modulus due to the decrease in the interlayer separation. Recently, Pipes and Hubert [264] have applied both textile mechanics and anisotropic elasticity to analyze a polymer matrix composites consisting of discontinuous CNTs assembled in helical geometry. The effective elastic properties were predicted and their study showed the strong dependence of the mechanical behavior on the helical angle of the assembly.

In the proposed experiment (Fig. 34), we will attach the bundles using our previously developed nanoclamping methods (Fig. 35) [11,29,265] and our new method of deposition of low electrical resistance W clamps. One goal involves measuring whether twisting enhances load transfer in terms of increased stiffness and strength. We will measure the bundle stiffness without twisting, and then as a function of twisting, in the low strain regime to assess the effective modulus of the bundle as a function of twist. To study the influence of twisting on strength, we will measure the load at break of similar diameter and length bundles with and without twisting, as a function of diameter, length, and number of twists. The boundary conditions will also be assessed. We expect that the carbonaceous deposit made by electron beam-

induced decomposition of residual hydrocarbons in the SEM, or the W deposit made, will (largely) be in contact with the outermost (perimeter) SWCNTs in the bundles. In untwisted perfect crystal SWCNT bundles having, for example, little load transfer to core SWCNTs from the perimeter SWCNTs and with only perimeter SWCNTs clamped (from the method of deposition of our nanoclamp), we should be able to measure if load bearing and breakage are occurring only at the perimeter SWCNTs. We should be able to differentiate this from the load transfer we hypothesize will take place upon twisting. One method of monitoring such effects would be to simultaneously monitor the electrical conductivity of the bundle during mechanical loading.

We have recently been developing methods for simultaneous measurement of the electrical conductivity of nanofilaments spanning the opposing AFM tip cantilevers, by using conductive AFM tip cantilevers and the W nanoclamp. We propose that such measurements will help to elucidate the dynamics of the nanobundle. The video-recording allows for a time resolution of only $\sim 1/30$ of a second, the time between video frames. However, electrical conductivity can be measured on a much finer time scale; doing so may allow us to infer when individual SWCNTs have broken prior to the whole bundle breaking, to study interlayer interactions between SWCNTs in the bundle as a function of twisting, and to study changes in conductivity that occur simply due to mechanical deformation of individual tubes in the bundle. Mapping out the electromechanical response of SWCNT bundles as a function of compressive, tensile, and torsional, loading will provide a database useful for assessing their application as actuators, sensors, and NEMS components. Measuring the electromechanical response in real applications such as cabling in a suspension bridge could also be a useful method of monitoring the reliability of nanorope components in everyday use.

5.2 Filling the nanotubes

The mechanical benefits of filling nanotubes with various types of atoms are the following:

- 1) Filling provides reinforcements for the hollow tube in the radial direction, thus preventing it from buckling, which from the discussion Section 2.2.3, is known to take place easily.

Fig. 34 Proposed experimental stage for twisting the nanoropes

Fig. 35 Home-built nanomanipulation testing stage, which fits in the palm of the hand and is used in a high resolution scanning electron microscopy. See Yu *et al* [11,28,29] for further details.

- 2) Filling provides the smoothest and smallest nano-bearing system.
- 3) Filling also provides an efficient storage system.

Currently, there are two major experimental techniques that fill the CNT with foreign materials: arc evaporation, in which foreign materials are put in the anode for their incorporation into the CNTs formed from the carbon plasma, or opening the CNT by chemical agents followed by subsequent filling from either solution-based transport or by vapor transport. Since the chemical and physical environment in the solution-based filling method is less intensive, fragile materials such as biomaterials can also be put into the CNTs using that method.

Early attempts to make filled CNTs using arc evaporation have also resulted in filled carbon nano-particles rather than filled CNTs. The foreign fillers include most metallic elements [266–277], magnetic materials [278–282] and radioactive materials [283,284], and are surrounded by a carbon shell. One of the most well-known commercial applications of such filled nano-particles is the invention of the so-called Technegas [285,286], which is essentially radioactive material coated with carbon and used as an imaging agent in the detection of lung cancer.

A major breakthrough in filling CNTs was made by Ajayan *et al* [287,288], in which CNTs were opened by an oxidation process and foreign materials (molten lead in their case) were drawn into the CNT due to capillary action. This is the first experiment that showed the possibility of opening the CNT, although the method used is not universally applicable. Numerous efforts have been undertaken along this direction, including combining oxidation with heating [288–290], and the use of liquid-based approaches, such as nitric acid [291], Hydrochloric acid [292], or other oxidants [293,294]. Using these processes and the arc evaporation method, different types of materials were also incorporated into CNTs, eg, compounds of metals or their carbides [269,291,295,296] and biological molecules [297,298], hydrogen [299], and argon [300]. Filling of SWCNTs was first reported by Sloan *et al* [292,301]. Experimental observation of fullerenes inside CNTs has also been reported by Smith *et al* [302–304] and Burteaux *et al* [305] using pulsed laser evaporation (PLV) of a graphite target containing a catalyst, and by Sloan *et al* [306] and Zhang *et al* [307] using arc vaporization of carbon with a mixed Ni/Y catalyst.

Filled CNTs have recently been treated by theory and modeling. Pederson *et al* [308] discussed the capillary effect at the nano-scale. A major topic is the effect of the change in the dimensionality (from 3D to 1D) and scale (from macroscale to nanoscale) on the resulting physical properties. The effect of the size of the CNT as a geometric constraint on the crystallization process is discussed by Prasad *et al* [309]. Tuzun *et al* studied flow of helium and argon [186] and mixed flow of helium and C_{60} [187] inside CNTs using MD. Berber *et al* [310] studied various configurations of putting C_{60} inside a CNT using an *ab initio* method. Stan *et al* presented analysis of the hydrogen storage problem [311]. The dif-

fusion properties of molecular flow of methane, ethane and ethylene inside CNTs were studied using MD by Mao *et al* [312].

A general analysis of the statistical properties of the quasi-one dimensional structure inside a filled CNT is treated by Stan *et al* [313]. The mechanics of C_{60} inside CNTs was studied by Qian, Liu, and Ruoff *et al* [213] using MD simulation. An interesting phenomenon is observed in which C_{60} is *sucked* into the (10, 10) or (9,9) SWCNTs by the sharp surface tension force present in the front of the open end, following which it then oscillates between the two open ends of the nanotube, never escaping (see Fig. 36). Moreover, the oscillation shows little decay after stabilizing after a few cycles. Both the C_{60} molecule and the nanotube show small deformations as a function of time and position. Furthermore, C_{60} , even when fired on axis with an initial speed up to 1600 m/sec, cannot penetrate into any of the (8,8), (7,7), (6,6), or (5,5) NTs. The simulation results suggest the possibility of using C_{60} in CNTs for making nano-devices such as nanobearings or nano-pistons. We continue to study this nanocomposite of fullerenes in CNTs.

Fig. 36 Computational modeling of C_{60} inside nanotubes: (a) The configuration for the problem, (b) The three velocity components history of the C_{60} as it shuttles through the (10,10) nanotube 20 times (V_z corresponds to the axial direction with an initial value of 0), and (c) Same as (b), but for the case of an (8,8) nanotube. 5.3 Nanoelectromechanical systems (NEMS)

5.3.1 Fabrication of NEMS

Nanoelectromechanical systems (NEMS) are evolving, with new scientific studies and technical applications emerging. NEMS are characterized by small dimensions, where the dimensions are relevant for the function of the devices. Critical feature sizes may be from hundreds to a few nanometers. New physical properties, resulting from the small dimensions, may dominate the operation of the devices. Mechanical devices are shrinking in size to reduce mass, decrease response time, and increase sensitivity.

NEMS systems defined by photolithography processes are approaching the dimensions of carbon nanotubes. NEMS can be fabricated with various materials and integrated with multiphysics systems such as electronic, optical, and biological systems to create devices with new or improved functions. The new class of NEMS devices may provide a revolution in applications such as sensors, medical diagnostics, functional molecules, displays and data storage. The initial research in science and technology related to nanomechanical systems is taking place now in a growing number of laboratories throughout the world.

Fig. 37 Before (upper) and after (lower) untangling the nanotubes in the suspension

The fabrication processes combine various micro/nano machining techniques including micro/nano structure fabrication and surface chemistry modification of such fabricated structures to allow site-specific placement of nanofilaments (NF) for actuation and sensing. Different kinds of NFs such as SWCNTs and MWCNTs, nanowhiskers (NWs) and etched nano-structures require different processing steps.

Controlled deposition of individual SWCNT on chemically functionalized templates was first introduced by Liu *et al* [314]. Reliable deposition of well-separated individual SWCNTs on chemically functionalized nanolithographic patterns was demonstrated. The approach offers promise in making structures and electronic circuits with nanotubes in pre-designed patterns.

SWCNTs generally exist as bundles when purchased, so they have to be dispersed into individual SWCNTs in a solution before being used for device experimentation. One controllable procedure is done by diluting the SWCNT suspension into N, N-dimethylformamide (DMF) at a ratio of 1:100. The vial is then sonicated in a small ultrasonic bath for 4-8 hours. Such steps are repeated at least 3 times until the clear suspension contains at least 50% of the SWCNTs completely separated as individual SWCNTs (Fig. 37).

Recently, Chung, Ruoff, and Lee [315] have developed new techniques for nanoscale gap fabrication (50–500 nm) and the consecutive integration of CNTs. These techniques are essential for the batch assembly of CNTs (diameter~10 nm) for various applications [29,265,316–320]. Figure 38 shows an ideal configuration for chemical sensing by electromechanical transduction involving only a single CNT. So far, they have successfully deposited CNT bundles across the circular gap based on micro-lithography (Fig. 39). The fabrication steps do not use serial and time consuming process such as e-beam lithography, showing the potential for batch production. It is also noted that these deposition steps were performed at standard environment conditions, thus providing more process freedom. Details of this new fabrication technique can be found in [315].

5.3.2 Use of nanotubes as sensors in NEMS

The small size and unique properties of carbon nanotubes suggests that they can be used in sensor devices with unprecedented sensitivity. One route to make such sensors is to utilize the electrical properties of CNTs. Experiment [321]

Fig. 38 Carbon nanotube-based sensor

and computation [322,323] have shown that the conductivity of CNTs can change by several orders of magnitude when deformed by the tip of an atomic force microscope. CNT chemical sensors have also been demonstrated: it has been found experimentally that the electrical resistance of a semi-conducting SWCNT changes dramatically upon adsorption of certain gaseous molecules, such as NO_2 , NH_3 [319], H_2 [324], and O_2 [318]. This phenomenon has been modeled numerically by Peng and Cho [325] using a DFT-LDA technique.

The high sensitivity of the Raman spectra of CNTs to their environment also makes them useful as mechanical sensors. Raman spectra are known from experiment to give shifted peaks when CNTs undergo stress or strain [326–328]. This phenomenon has been used to detect phase transitions and to measure stress fields in polymers with embedded nanotubes [329,330].

Yet another interesting application of nanotubes as sensors is through the use of the mechanical resonance frequency shift to detect adsorbed molecules or groups of molecules. When the mass of a vibrating cantilever changes, as by the addition of an adsorbed body, the fundamental frequency of the cantilever as described by Eq. (2) decreases. Ilic *et al* [331] demonstrated micromachined silicon cantilevers with typical dimensions on the order of $20\ \mu\text{m} \times 320\ \text{nm} \times 100\ \mu\text{m}$ to detect *E. coli* cells; the device was shown sensitive enough to detect as few as 16 cells under atmospheric conditions. Because the sensitivity of the device is hampered by the mechanical quality factor Q of the oscillating cantilever, even greater sensitivity might be expected in vacuum where the lack of air damping enables higher Q ; of course operation in vacuum limits the utility of the device. Shrinking the size of the design by using a carbon nanotube rather than a micromachined cantilever may give unprecedented sensitivity.

Poncharal *et al* [44] were able to use the resonant frequency of a vibrating cantilevered nanotube (Fig. 18) to estimate the mass of a $\sim 30\text{fg}$ carbon particle attached to the end of the tube. Our own calculations predict that detection of a 1% change in the resonant frequency of a 100 nm-long (10,10) CNT allows the measurement of an end mass of

around 800 amu, approximately the mass of a single C_{60} molecule. The frequency shift of a vibrating cantilevered CNT due to an adsorbed mass at the free end can be estimated using beam theory (Section 2.2.2). To the first order approximation, the change in resonance frequency of mode i is

$$\Delta f_i = -\frac{2Mf_i}{\rho AL} \quad (48)$$

where M is the mass of the adsorbed body and ρ , A , and L are respectively the density, cross-sectional area, and length of the CNT. Sensitivity may be even further enhanced by taking advantage of critical points in the amplitude-frequency behavior of the vibrating CNT. For example, it is likely that the nonlinear force-deflection curve of the nanotube under certain conditions can result in a bistable response, as has been seen for other vibrating structures at this scale [332]. The dependence of force on displacement can also lead to parametric resonance and associated regions of instability that can be used to highlight small changes in vibration frequency [333,334]. Recently, we have measured 4 parametric resonances of the fundamental mode of boron

Fig. 39 CNT deposition in a round gap by AC electrophoresis

Fig. 40 Upper: In situ TEM image of crack in polystyrene film with nanotubes bridging the crack; Lower: arrangement of nanotubes in polymer, good dispersion, random orientation and moderate waviness [337]

nanowires, the first observation of parametric resonance in a nanostructure [334]. It is likely that extraordinarily sensitive molecular sensors can be based on exploiting the parametric resonances of nanostructures (such as nanotubes, nanowires, or nanoplatelets).

5.4 Nanotube-reinforced polymer

The extremely high modulus and tunable electrical and thermal properties of carbon nanotubes offer an appealing mechanism to dramatically improve both strength and stiffness characteristics, as well as add multifunctionality to polymer based composite systems. Experimental results to date, however, demonstrate only modest improvement in important material properties amidst sometimes contradictory data [335–339]. Much of the discrepancy in the published results can be attributed to nonuniformity of material samples: in order to obtain optimal property enhancement, key issues to be resolved include improved dispersion of nanotubes, alignment of nanotubes, functionalization of the nanotubes to enhance matrix bonding/load transfer, and efficient use of the different types of nanotube reinforcements (single wall versus nanorope versus multiwall).

Ongoing investigations are focusing on improved processing and design of nanocomposites with emphasis on controlled nanotube geometric arrangement. Techniques to obtain homogeneous dispersion and significant alignment of the nanotubes include application of electric field during polymerization, extrusion and deformation methods [340–342]. In addition to dispersion and alignment, recent work [343,344] has demonstrated that the waviness of the nanotubes (see Fig. 40) in the polymer decreases the potential reinforcing factor by an additional 50% beyond a two-fold decrease due to random orientation.

Among the encouraging results is work by Qian [337] for a MWCNT reinforced polymer where good dispersion and matrix bonding was achieved. In this case, using only 0.5 vol % nanotube reinforcement with no alignment and moderate NT waviness, elastic stiffness was improved 40% over that of the neat matrix material and strength values improved nearly 25%. Figure 40 shows nanotubes bridging a matrix crack and demonstrates excellent bonding between

nanotubes and matrix material. Viscoelastic properties have also been investigated, with some evidence that well dispersed nanotubes impact the mobility of the polymer chains themselves, causing changes in glass transition temperature and relaxation characteristics [345,346], a feature not observed in polymers with a micron sized reinforcing phase. Limited work on electrical properties shows that percolation can be reached with nanotube volume fractions of less than 1% [335], leading to dramatic changes in electrical response of the polymer. This enables applications such as polymer coatings with electrostatic discharge capability [347].

Understanding the mechanisms involved and the degree of property improvement possible for nanotube reinforced polymers remains a goal of intensive research. Current work emphasizes surface modification of CNTs; control of matrix-NT adhesion; processing methods to control nanotube geometry; hybridization of nano and microscale reinforcements; multifunctional capabilities; and integration of atomistic, micromechanics and continuum modeling for predictive capability and understanding.

The multiscale method described in Section 4.3 shows great potential in the analysis and modeling of nanotube-reinforced material. Shown in Fig. 41 is an illustration of the approach, combined with the nanorope application discussed in Section 5.1. In this method, the domain of the problem is decomposed into three regions: 1) the coarse scale region, 2) the coupling scale region and 3) the fine scale region. We will solve the coupled equation (Eqs. (47a) and (47b) based on the area of interest. A unique advantage of this method is the multiscale decomposition of the displacement field. The governing equations for continuum scale and molecular scale are unified and no special treatment is needed in handling the transition. More details of the modeling approach is included in [348].

6 CONCLUSION

The development of successful methods for the synthesis of high quality CNTs [86] has led to a world-wide R&D effort in the field of nanotubes. Part of the focus in this paper has been to address the particularly promising mechanical attributes of CNTs as indicated in numerous experiments, with emphasis on the inherent high stiffness and strength of such nanostructures. As stated in Section 3.3, much work still remains on the experimental measurement of the mechanical properties of CNTs. Progress made on the theoretical and computational fronts has also been briefly summarized.

It is amazing to see the applicability of continuum elasticity theory even down to the nanometer scale, although this fact should not lead to overconfidence in its use, or to any ignorance of the physics that lies beneath. There are also a lot of unresolved issues in theoretical analysis and simulation due to the highly cross-disciplinary nature of the problem. In fact, numerous research efforts are underway in developing multi-scale multi-physics simulation schemes. These efforts depend largely on gaining a basic understanding of the phenomena from the quantum level to the continuum level. Therefore, the term *nanomechanics* or *nano-scale mechanics*

Fig. 41 Multiscale analysis of nanorope reinforced materials

indeed goes beyond the nano-scale and serves as a manifestation of the link between fundamental science and important engineering applications. This is a major challenge for the engineering community as well as the science community in the sense that the traditional boundary of each field has to be redefined to establish the new forefront of nano-technology. A number of applications that are described in Section 5 serve as the best examples. Yet there are still numerous other likely applications of CNTs that we would like to mention; for instance, there has also been interesting research on the use of CNTs as ferroelectric devices, nano-fluidic devices, and energy storage devices, and there exists the possibility of their use in bio-surgical instruments. We have not been able to address these topics due to time and space limitations.

As we try to give an up-to-date status of the work that has been done, the field is rapidly evolving and a tremendous amount of information can be found from various media. It is conceivable that the discovery of carbon nanotubes and other multifunctional nanostructures will parallel the importance of the transistor in technological impact. The size and the mechanical, electrical, thermal, and chemical properties of CNTs, as well as the fact that they are hollow and that matter can thus be located inside them and transported through them, have suggested an astonishingly wide array of potential applications, many of which are under testing now. Statements [349] are being made about factories being set up with ton-level production capabilities. We believe the unique structure and properties of CNTs and related nanomaterials will bring a fundamental change to technology.

Acknowledgment

RSR appreciates support from the NASA Langley Research Center Computational Materials: Nanotechnology Modeling and Simulation Program, and support to GJW, RSR, and WKL from the ONR Miniaturized Intelligent Sensors Program (MIS) and from the grant: Nanorope Mechanics, NSF (Oscar Dillon and Ken Chong, Program Managers). The work of DQ and GJW has also been supported by the Tull Family Endowment. RSR and WKL have, for some of the work described here, been supported by several grants from NSF. DQ also acknowledges the support of the Dissertation Year Fellowship from Northwestern University. The contributions from Junghoon Lee, Jae Chung, and Lucy Zhang, of Northwestern University, (also supported by ONR MIS) on NEMS (Section 5.3.1) and from Cate Brinson (also supported by the NASA Langley Research Center Computational Materials: Nanotechnology Modeling and Simulation Program) on nanotube reinforced polymers (first four paragraphs of Section 5.4) are gratefully acknowledged.

Dong Qian received his BS degree in Bridge Engineering from Tongji University in Shanghai, China in 1994. He came to the United States in 1996 and received his MS degree in Civil Engineering from University of Missouri-Columbia in 1998. From 1998–2002, he conducted PhD study in Mechanical Engineering at Northwestern University, under the supervision of Prof Wing Kam Liu (co-advised by Prof Rodney S Ruoff). He is currently an Assistant Professor in the Department of Mechanical, Industrial, and Nuclear Engineering at the University of Cincinnati. His research interests include nano-scale modeling, simulation and applications, meshfree methods, and development of multi-scale methods in solid mechanics.

Gregory J Wagner is a member of the Chemistry and Materials Process Modeling group at Sandia National Laboratory in Livermore, CA. He previously held the position of Research Assistant Professor in the Mechanical Engineering Department at Northwestern University, where he received his PhD in 2001 with a thesis on the simulation of fluid/particle suspension flows. He also holds an MS-ME from Northwestern and BS-ME from Boston University. He is a member of ASME.

Wing Kam Liu received his BS with the highest honor from the University of Illinois at Chicago (1976); his MS (1977) and PhD (1981) from Caltech. In September 1980, he became an Assistant Professor at Northwestern University. In 1988, he became a Professor of Mechanical and Civil Engineering. His research activities include development of finite element methods, reproducing kernel and wavelet methods and deterministic and probabilistic computational methods, design and manufacturing and nano-mechanics. He is the recipient of the 2001 Computational Structural Award from USACM, 1995 Gustus L Larson Memorial Award from ASME, 1989 Thomas J Jaeger Prize, IASMiRT, 1985 Pi Tau Sigma Gold Medal from ASME, the 1983 Ralph R Teeter Educational Award from ASAE and the 1979 Melville Medal from ASME. He became a Fellow of ASME in 1990, ASCE in 1993, and USACM in 1995. Currently, Liu serves as an Associate Editor for the ASME Journal of Pressure Vessel Technology, and the ASME Journal of Applied Mechanics, Managing Editor of Computers and Structures, and Computational Mechanics, and Advisory Editor of Computer Methods in Applied Mechanics and Engineering. He is the current President of the United States Association for Computational Mechanics. In 2001, Liu was listed by the Institute for Scientific Information (ISI) as one of the most highly cited, influential researchers in engineering, and an original member of the highly cited researcher database. He is the recipient of the 2002 Computational Mechanics Award from the International Association for Computational Mechanics.

He is the current President of the United States Association for Computational Mechanics. In 2001, Liu was listed by the Institute for Scientific Information (ISI) as one of the most highly cited, influential researchers in engineering, and an original member of the highly cited researcher database. He is the recipient of the 2002 Computational Mechanics Award from the International Association for Computational Mechanics.

Min-Feng Yu is an Assistant Professor of Mechanical and Industrial Engineering at the University of Illinois at Urbana-Champaign. He previously (2000–2002) held the position of staff scientist at Zyvex Corporation in Richardson, Texas. Yu received his BS degree from University of Science and Technology of China in 1992, MS degree from Fudan University in 1997 and his PhD degree in Physics from Washington University in St Louis in 2000. He has more than twenty scientific publications and is a member of APS, MRS, and AAAS.

Rodney S Ruoff is a Full Professor in the Mechanical Engineering Department at Northwestern University, where he teaches a variety of courses on nanotechnology and performs research on the broad range of possible mechanics exhibited by nanostructures. He previously (1996–2000) held the position of Associate Professor in the Department of Physics at Washington University in St Louis; prior to that was a staff scientist at the Molecular Physics Laboratory of SRI International (1991–96). Ruoff received his PhD in 1988 in Chemical Physics at the University of Illinois-Urbana, advised by Prof Herbert S Gutowsky. He received a Fulbright Fellowship to work at the MPI-fuer Strömungsforschung in Goettingen, Germany, returning to the United States for a postdoc at IBM-Watson Research Laboratory in Yorktown Heights, NY (1989–91). He has approximately 145 publications and holds five patents. Ruoff's world wide web home page is <http://bucky-central.mech.nwu.edu/>.
